Figure 3 Mechanism of tissue injury in IBD. Inflammatory processes can be dramatically increased by a variety of mechanisms, including: 1) direct activation of granulocytes or neutrophils by bacterial products, 2) priming of phagocytes directly by IgG, or 3) specific immunological effector events mediated by IgG activation of the complement cascade. After priming or activation of granulocytes and macrophages, a host of destructive inflammatory mediators and toxic oxygen radicals can lead to direct tissue damage by a variety of destructive mechanisms. The two primary agents used to treat IBD patients (steroids and 5-ASA products) are effective because of their ability to inhibit many of the pathways that lead to inflammation-induced injury. (Adapted with permission from Scriber S, Raedler A, Stenson WF and MacDermott RP (1992) The role of the mucosal immune system in inflammatory bowel disease. In: MacDermott RP and Elson CO (eds) *Gastroenterology Clinics of North America*, 21: 453. Philadelphia: WB Saunders.)

ative colitis. The spontaneous secretion of IL-1 β is increased in intestinal lamina propria mononuclear cells isolated from IBD patients when compared with normal controls.

Lipopolysaccharide further enhanced IL-1 β production by IBD lamina propria mononuclear cells, but not by those from normal controls. Increased IL-1 concentrations play a key role in the pathogenesis of rabbit immune complex colitis, and tissue levels of IL-1 correlate with the severity of inflammation. Lamina propria mononuclear cells isolated from endoscopic biopsy specimens from patients with active IBD spontaneously secrete high amounts of IL-1 β .

Using polymerase chain reaction, higher levels of IL-1, IL-6, and TNF α mRNA have been demonstrated in Crohn's disease and ulcerative colitis patients than in normal subjects. MacDonald and colleagues using a spot ELISA technique, demonstrated that TNF α -secreting intestinal mononuclear cells are increased in frequency in both Crohn's disease and a subgroup of ulcerative colitis patients in comparison with normal controls. These obser-

vations have therapeutic implications because antibodies against TNF α are now undergoing trials as a form of treatment.

The spontaneous secretion of IL-6 is increased by lamina propria mononuclear cells from ulcerative colitis patients. This secretion appears to be less marked in Crohn's disease than in ulcerative colitis. Many of the biologic activities of IL-1, IL-6, and TNF α that amplify inflammatory and immunological processes overlap. Therefore, sustained inflammation leading to tissue destruction in IBD could potentially be mediated by the potent proinflammatory activities of IL-1 α , IL-1 β , IL-6, and TNF α (Figure 4).

The role of chemotactic cytokines in the pathophysiology of ulcerative colitis and Crohn's disease has just begun to be examined. Chemokines may play an important role in the perpetuation of inflammation in IBD because, in contrast to other chemoattractant molecules, such as leukotriene B₄ (LTB₄), formyl-Met-Leu-Phe (fMLP) and PAF, they are relatively resistant to inactivation *in vivo*. Furthermore, chemokines are rapidly produced by a number of different cell types after stimulation by proinflammatory

Figure 4 Phagocytic activation and inflammatory events in IBD. Bacterial cell wall products from the intestine prime monocytes and granulocytes to increase the expression of adhesion molecules with increased recognition of endothelial cell receptors. Macrophages and granulocytes migrate from the capillaries and venules into the intestinal lamina propria, from which they migrate into the intestinal lumen through the intestinal wall. The primed macrophages and granulocytes within the intestinal lamina propria are activated by bacterial cell wall products, such as LPS, as well as by antigenic luminal factors to release a variety of proinflammatory cytokines and mediators including IL-1, TNF α , IL-6, PAF, leukotrienes and prostaglandins (PG/Tx). In addition, destructive molecules, such as oxygen radicals and proteases, are produced. The involvement of granulocytes and macrophages in IBD adds an acute inflammatory component to the chronic cell-mediated intestinal injurious processes involved in IBD.

cytokines. Chemokines are relatively resistant to inactivation and have comparatively long half-lives *in vivo*. They are secreted by many different cell types and have specific chemotactic activities with regard to defined subtypes of leukocytes. Therefore, chemokines may play pivotal roles in the perpetuation and upregulation of the chronic inflammatory processes in ulcerative colitis or Crohn's disease patients (Figure 4). IL-8, an α -chemokine, is a potent neutrophil chemoattractant and activator. Increased synthesis and production of IL-8 is present in ulcerative colitis. Very high levels of IL-8 mRNA have been observed in involved ulcerative colitis mucosa and moderately increased IL-8 mRNA levels in involved Crohn's disease mucosa. Involved intestinal mucosal sections exhibited higher levels of IL-8 mRNA than noninvolved mucosal sections obtained from the same patients. Monocyte chemoattractant protein 1 (MCP-1), a β -chemokine and a potent monocyte chemoattractant and activator, is also increased in inflammatory bowel disease.

Prostaglandin production

Prostaglandins are synthesized from arachidonic acid catalyzed by the enzyme cyclooxygenase. Prostaglandins, particularly the E series, have biologic properties that can enhance microvascular permeability with subsequent edema, vasodilatation and

induction of pain. In IBD, there is an increased level of prostaglandin production. Elevated levels of prostaglandins are found in the stool, venous blood and rectal mucosa in IBD. Prostaglandin levels in IBD in mucosa, serum or rectal dialysates correlate with disease activity. Successful medical management results in reduction in prostaglandin levels.

There is some evidence, however, that contradicts the role of prostaglandins as proinflammatory mediators in IBD. The use of potent cyclooxygenase inhibitors, indomethacin and other nonsteroidal anti-inflammatory drugs (NSAIDs), results in both a decrease in prostaglandin synthesis and in clinical improvement in rheumatoid arthritis and other inflammatory diseases. However, NSAIDs have no role in the medical management of IBD. Small trials of indomethacin administered orally or rectally revealed no improvement in ulcerative colitis. Some reports have shown that both indomethacin and flurbiprofen may cause clinical deterioration despite causing a decrease in prostaglandin production. The failure of NSAIDs to induce clinical improvement in IBD suggests that the secretion of prostaglandin and other inflammatory mediators such as PAF, leukotrienes and proinflammatory cytokines including chemokines, must be inhibited concurrently to reduce tissue injury.

Leukotriene synthesis

Leukotrienes are derived from arachidonic acid via the 5-lipoxygenase pathway found primarily in cells of bone marrow origin involved in the inflammatory process, including mast cells, neutrophils, monocytes and macrophages. The major products of this pathway are 5-hydroxy-6,8,11,14-eicosatetraenoic acid (5-HETE) and leukotrienes B₄ (LTB₄), C₄ (LTC₄), D₄ (LTD₄), and E₄ (LTE₄). LTB₄ and 5-HETE are potent neutrophil chemoattractants. LTB₄ also increases vascular permeability. The sulfidoleukotrienes (LTC₄, LTD₄, LTE₄) induce smooth muscle contraction in the lung, blood vessels and gastrointestinal tract.

IBD mucosa produces larger quantities of lipoxygenase and cyclooxygenase products than normal mucosa. Lipid extracts of IBD mucosa contain large amounts of LTB₄, up to 50-fold as much as normal mucosa. Levels of LTB₄ are markedly higher in rectal dialysates from ulcerative colitis patients and decrease to normal levels after treatment with prednisolone. Crohn's colitis mucosa produces a three-fold increase in sulfidoleukotrienes (LTC₄, LTD₄, LTE₄) compared to normal mucosa.

Conclusions

In IBD, the state of activation of the intestinal immune system and mucosal inflammatory pathways are markedly upregulated. The mechanisms that normally downregulate the immunologic and inflammatory protective processes, once the inflammatory stimulus has been cleared, appear to be deficient or are suboptimal. Knockout mice that do not express IL-10, a cytokine that normally downregulates immune responses, have a number of features of inflammatory bowel disease. It is possible that

changes in immunological responsiveness in IBD are genetically controlled. A critical area of investigation is the elucidation of the genetic factors that predispose certain individuals either to having a heightened immune and inflammatory response or an inability to downregulate ongoing chronic immunologic and inflammatory events.

INFLAMMATORY BOWEL DISEASE, ANIMAL MODELS

Uzma Shah and Ian R Sanderson, Combined Program in Pediatric Gastroenterology and Nutrition, Massachusetts General Hospital, Boston, Massachusetts, USA

Environmental, immune and genetic susceptibilities have all been implicated in the pathogenesis of inflammatory bowel disease (IBD). The development of various experimental models (Table 1) has enabled researchers to study the development of inflammation in the intestine, under conditions where the underlying lesion is better understood.

Using recombinant DNA technology to target gene insertions and deletions, mutant animals with known genetic abnormalities are produced. Exogenous agents such as chemicals, bacterial products and immune complexes have also been used in animal models of disease. These models also serve as tools to study therapeutic strategies in IBD.

Table 1 Models of IBD*Genetically engineered*

Dominant negative N-cadherin in intestinal epithelia
 IL-2 deficient
 IL-10 deficient

Animal models of inflammation induced by gene disruption

Dominant negative N-cadherin mutants

Cadherins are transmembranous glycoproteins that mediate cell adhesion. The cytoplasmic domain of N-cadherin includes a β -catenin which, in turn, binds an α -catenin. The catenin-cadherin complexes regulate a variety of cell functions, including proliferation, polarity and migration. Disruptions of these interactions result in the development of IBD that closely resembles Crohn's disease. Chimeric mice, generated from normal blastocysts and genetically manipulated embryonic stem (ES) cells, have been used to study N-cadherin function. These B6 $\leftrightarrow$ 129 SV chimeric mice have patches of ES cell-derived, as well as the normal B6-derived, crypt villous units. The ES cell lineage is distinguished from the B6 cells by their ability to bind to *Ulex europaeus* agglutinin type 1. Promoters are available that specifically express genes localized to the intestinal epithelium. ES cells transfected with such a promoter, the fatty acid binding promoter (Fabpi), linked to the negative cadherin (NCAD) was used to generate B6 $\leftrightarrow$ 129 SV NCAD chimeras. Expression of the dominant mutant resulted in loss of endogenous E-cadherin, cell-to-cell adhesion and promoted early entry of epithelial cells into programmed cell death. E-cadherin is normally localized to the basolateral surface of intestinal epithelial cells and apical junctional complexes. Changes, confined to the intestine covered by the ES cell-derived epithelium (which expresses

NCAD) include lamina propria infiltration with lymphocytes and histiocytes, immunoglobulin A (IgA)- and IgG-secreting plasma cells and increased expression of class II major histocompatibility complex (MHC). By 3 months of age, crypt distortion and crypt abscesses appear. Chimeras expressing NCAD along the entire crypt villous axis have greater disease than those with NCAD expression confined to the villous epithelium. In these animals, intestinal dysplasia and neoplasms can also be seen. This animal model exemplifies the importance of the epithelial barrier in the prevention of IBD.

IL-2 knockout mice

Interleukin-2 (IL-2) activates macrophages, lymphokine-activated killer (LAK) cells and natural killer (NK) cells and induces differentiation of B cells, in addition to promoting growth and expansion of T cells. In a study of the function of IL-2 in mice by gene disruption, it was noted that these mice develop a lesion that is similar in many ways to ulcerative colitis. IL-2 knockout mice develop normally until 4 weeks of age. Approximately half die after the first month of age, mainly from anemia, while those surviving more than 10 weeks develop a pancolitis characterized by bloody diarrhea and rectal prolapse. Colonic wall thickening, ulceration, crypt distortion and abscesses are seen on histological examination. Immune abnormalities in the lamina propria include an increase in activated T cells (as demonstrated by markers for CD44 and CD69), in activated B cells and in MHC class II expression, suggesting both T and B cells are stimulated in the colonic immune response. No bacterial pathogen has been identified but germ-free animals do not develop disease, suggesting that an abnormal immune response to enteric flora contributes to the pathogenesis of IBD.

IL-10 knockout mice

Derived from T cells, macrophages and certain B cells, IL-10 is a potent inhibitor of macrophages and T_H1 lymphocytes. IL-10-deficient mice, generated by gene disruption in ES cells, develop intestinal disease resembling IBD, with both small and large intestinal involvement. The enterocolitis is segmental and associated with a chronic inflammatory infiltrate. Loss of epithelial integrity is also present, and there is an increase in class II MHC expression. The disease is ameliorated, but not eradicated by housing mice in a pathogen-free environment, as focal proximal colitis is still evident. Resolution, however, occurs on administration of IL-10 antagonists, suggesting that an aberrant T_H1 cell response, normally inhibited by IL-10, may be responsible.

T cell receptor and MHC class II mutants

Chronic colitis resembling human ulcerative colitis is observed in mice that do not express normal T cell receptors on the T cell surface resulting from an introduced mutation in the β chain. In contrast, disruption in the recombinant activating gene RAG1, which results in animals lacking both B and T cells, does not result in bowel inflammation. Increased B cell activation is observed in the T cell receptor mutant mice with an increase in IgA, IgM and IgG secretion, perhaps due to a lack of T cell-mediated suppression of B cells. MHC class II^{-/-} mice which lack class II-restricted CD4⁺ T cells also develop bowel inflammation, again implicating a loss of immunoregulatory T cells in the development of the disease. The mice with these lesions predominantly exhibit colonic disease. Histological sections show mucin depletion, crypt distortion and a mixed inflammatory histology. Ulceration, granulomas and fibrosis are not seen. The incidence and severity of the disease vary with the genetic background of the mice examined, implying that other genes modify disease susceptibility.

G α_{12} knockout

G protein heterodimers of α , β and γ chains serve as mediators of signal transduction for numerous surface receptors. G α_{12} is widely distributed in intestinal epithelial cells and in lymphocytes. Its functions include activation of MAP kinase, stimulation of tumor necrosis factor α (TNF α) and production of colony-stimulating factor 1. Mice with an introduced deletion of G α_{12} develop pancolitis by 8–12 weeks of age. Approximately a third of the animals develop adenocarcinoma by 15–33 weeks of age. There is an increase in CD4⁺ T cells, and B cells. Unlike the knockouts of IL-2, IL-10 and the T cell receptor, pathogen-free mice continue to develop a pancolitis; however, variation in genetic background affects disease susceptibility.

CD45RB

The T cell and B cell deficiency in SCID mice can be reconstituted by B cell and T cell transfer. If the transferred CD4⁺ T cells express high levels of CD45RB (CD45RB^{hi}), the recipient mice exhibit a diarrhea which is chronic but does not contain blood. Transfer of CD4⁺ cells with low levels of CD45RB (CD45RB^{lo}) does not induce the disease, indeed CD45RB^{lo}, when cotransferred with CD45RB^{hi}, abrogates the disorder. Murine IL-10, interferon γ (IFN γ) and TNF α administration prevents the disease, while antibiotics abrogate the colitis, suggesting a role for bacterial pathogens in the development of the disease.

HLA-B27 transgenic rats

Expression of the human MHC class I haplotype HLA-B27 in rats results in an animal that develops enterocolitis resembling IBD. These rats also exhibit arthropathies in addition to the gastrointestinal lesions. The disease is abrogated in germ-free animals, again suggesting a role for normal colonic bacteria in the pathogenesis of inflammation. The colitis can be transferred to healthy controls by bone marrow cells derived from B27 transgenic rats. Transgenic mice expressing HLA-B27 do not show any abnormal phenotype, suggesting that the genetic background is important. This model, which was the first of the transgenic IBD models to be developed, demonstrates the interrelationship between a specific gene, the environment (bacterial flora) and the genetic background of the animal.

Models of spontaneous colitis

C3H/HeJ Bir mice

A spontaneous colitis occurs in a selective strain of C3H/HeJ mice noted at the Jackson laboratories to have diarrhea and rectal ulceration. The disease coincides with the onset of bacterial colonization and is focal in distribution. It spontaneously resolves as the mice age. The severity of the disease is variable and depends on the animal facility in which the mice are housed.

Cotton top tamarin

A remitting and relapsing colitis arises spontaneously in the cotton top tamarin by the second year of life. This disease, which appears to be found only in animals in captivity, shows considerable similarities to ulcerative colitis. The entire colon is involved. Serum antibodies to gut epithelial cells have been detected but no pathogen has been isolated. The intestinal epithelium exhibits an increased dysplasia with age. Again this animal shows the importance of the interaction between genetics and environmental factors in the development of disease. Some researchers have suggested that it may be a model in which the effects on the severity of colitis of neurogenic and stress factors can be studied.

Intestinal inflammation induced by exogenous agents

Trinitrobenzene sulfonic acid-induced colitis

Administration of an enema containing trinitrobenzene sulfonic acid (TNBS) results in the development of colitis in animals studied. The colitis has the

features of a delayed-type hypersensitivity response to TNBS. Variations are seen in the response amongst different strains of mice, and mice could potentially be used to define genes that control susceptibility of disease. These mice have responded well to drugs used in the treatment of IBD and provide a useful model with which to study newer modalities of treatment.

Acetic acid-induced colitis

Rectal irrigation of Sprague Dawley rats with 1 ml of 4% acetic acid results in epithelial injury and necrosis. The model, although lacking in chronicity, is useful for studying anti-inflammatory drugs. Mice given butyric acid also exhibit colitis, but it is not clear whether this is due to a different mechanism from acetic acid because butyric acid is a much weaker acid; butyrate itself has specific effects on intestinal epithelial cells.

Immune complex/formalin colitis

A model of colitis is seen when 0.45% unbuffered formaldehyde is inserted rectally with 0.85 ml of immune complexes injected into the ear vein of New Zealand white rabbits. The distal colitis is associated with crypt distortion, abscess formation, increased production of IL-1 and leukotriene B₄. Attenuation of the disease is seen when IL-1 antagonists are given, suggesting a central role for this cytokine in the disease. In addition sulfasalazine, mesalamine and azathioprine (all agents effective in treating IBD) decrease the severity of the colitis.

Indomethacin

Dose-dependent ulceration is seen in rodents given subcutaneous injections of indomethacin. Chronic intestinal inflammation results and is associated with extra intestinal manifestations of hepatic inflammation, anemia and leukocytosis. Prostaglandins appear to be protective, while bacteria may promote the inflammatory response. Sulfasalazine, metronidazole and IL-1 antagonists attenuate the disease.

Complex carbohydrate molecules

Guinea pigs given drinking water with 5% degraded carrageenan develop cecal inflammation in 5–7 days. Germ-free animals do not develop disease. The inflammation resolves with sulfasalazine and mesalamine. The model provides insights into possible interactions between endogenous bacterial flora and dietary constituents in the gut.

Cyclical administration of 5% dextran sulfate results in a chronic intestinal inflammation in Swiss Webster mice. Again IL-1 receptor antagonists will

ameliorate the disease. Luminal cyclosporine is also beneficial, while metronidazole prevents colonic inflammation and dysplasia.

Lewis rats given intramural injections of peptidoglycan-polysaccharide polymers develop an enterocolitis associated with granulomatous hepatitis, arthritis and anemia. Cecal mRNA for IL-1, IL-6 and cytokine-induced neutrophil chemoattractant (CINC/GRO) are increased. Cyclosporine and steroids aid in resolution of the disease.

Conclusions

Many factors are important in the pathogenesis of inflammatory bowel disease in humans and these include genetic susceptibility and environmental factors. A recurring characteristic of the animal models used to study inflammatory bowel disease is that, here too, both genetic background and environmental effects, particularly bacterial flora, appear to be important. Animal models with intestinal disease that have similarities to IBD thus provide one avenue for the study of the factors and their interaction. The use of these models provides information that not only illuminates our understanding of IBD but also aids in the development of therapeutic strategies.

INFLUENZA VIRUS (ORTHOMYXOVIRUS), INFECTION AND IMMUNITY

Robert G Webster, Peter C Doherty and Ralph A Tripp, St Jude's Children's Research Hospital, Memphis, Tennessee, USA

The orthomyxovirus family of segmented RNA viruses is classified into three types (A, B and C), based on differences between the internal matrix (M) and nucleoproteins (NP). Influenza A and B viruses have eight RNA segments while influenza C has seven, each coding for at least one protein. The following deals solely with the A viruses, which have received the most attention because changes in their surface hemagglutinin (HA) and neuraminidase (NA) glycoproteins lead to repeated epidemics and pandemics. The B and C viruses do not vary in this way.

The influenza A viruses comprise at least 15 HA and nine NA subtypes, all of which are found in birds. There are three HA subtypes in humans, two in pigs, two in horses, and occasional isolations from seals, mink and whales. Severe outbreaks of influenza have occurred in many of these species, with the 1918 epidemic killing more people than the preceding European war.

Infection and humoral immunity

Influenza in mammals, including humans, is essentially an aerosol infection confined to epithelial cells in the upper and lower respiratory tract. The disease

in birds is different, being largely gastrointestinal in nature and spread by fecal contamination. Some of the avian viruses (H5 and H7) are so virulent that death may result from generalized infection with central nervous system involvement.

Mucosal (IgA) and serum (IgG) antibodies to the HA molecule neutralize virus infectivity and are primarily responsible for resistance to reinfection. This is the basis of vaccination against current epidemic strains with killed virus. The immunoglobulin (Ig) response to the HA is subtype specific, but accumulation of point mutations (antigenic drift) permits infectious virus to escape antibody-mediated destruction. Five antigenic sites, all of which are associated with protection, have been identified on the globular head of the HA molecule. 'Antigenic drift' results from the accumulation of amino acid substitutions at these sites, reproduced in the laboratory by selection of escape mutants with mouse monoclonal antibodies (mAbs). In addition, crystallographic studies with the mutants have shown that the antibodies bind to the regions of the molecule where the amino acid substitutions occur.

Antibodies to the neuraminidase do not prevent infection but reduce the spread of virus. The enzyme-

active centers on each of the four subunits of the NA lie in a central cavity surrounded by two antigenic sites. Escape mutants can again be selected with mAbs to these sites, which inhibit virus release by blocking enzyme activity. Complexes of NA–Fab have been crystallized and their structure established. Each defines an epitope comprising five polypeptide loops on the NA, involving about 22 amino acids in direct contact.

Variability is the key feature of the influenza A viruses. This depends on two, separate mechanisms. Antigenic drift (see above) gives rise to variants of existing epidemic strains which are sufficiently different from their predecessors to escape neutralization by the Ig pool available in the population at risk. The more profound change associated with ‘antigenic shift’ may result from a chance dual infection with a human and an animal influenza A virus. Reassortment of the segmented genomes of the two viruses can then lead to the emergence of a novel pandemic strain, for which there is no pre-existing antibody in humans. Such reassortants are readily generated experimentally.

Cell-mediated immunity (CMI)

The current paradigm is that influenza A viruses are normally cleared from the infected lung by CD8⁺, virus-immune cytotoxic T lymphocytes (CTLs). Lymphocytes of this subset are driven to recognize virally infected cells by antigen-presenting cells expressing viral peptides in the context of major histocompatibility complex (MHC) class I glycoproteins to the T cell receptor (TCR) and by subsequent interaction of the CD8 molecule with the constant region of the MHC glycoprotein which is believed to increase the overall avidity of the interaction. Adoptive transfer experiments with T cell clones specific for one, but not another influenza A virus used to doubly infect mice, indicate that immune elimination depends on direct contact between the effector lymphocyte and the virus-infected target cell. This is generally thought to operate via a Ca²⁺-dependent lytic degranulation pathway mediated by perforin and granzymes. There is no ‘bystander’ destruction of adjacent cells infected with the virus that is not recognized. Most cytolytic T cells are also capable of lysis by a largely Ca²⁺ and pore-forming independent mechanism utilizing as the Fas–Fas ligand interactions. Recent experiments have shown that CD8⁺ T cells can clear influenza virus via perforin/granzyme or Fas-dependent processes.

Immune CD4⁺ T cells contribute to the lung consolidation characteristic of influenza pneumonia, and also play a significant role in virus clearance. Cloned,

CD4⁺ T cell lines can eliminate virus from the lung in the apparent absence of primed CD8⁺ lymphocytes. Cytolytic CD4⁺ T cells can be generated *in vivo*, though such generation is dependent on depletion of CD8 T cells. The Fas–Fas ligand pathway of cytotoxicity is believed to have a more prominent role in CD4⁺ versus CD8⁺ T cell-mediated cytotoxicity.

The one task that can be definitely attributed to the CD4⁺ population is help for antibody production, which is now known to be the mechanism underlying the clearance of virus from the lung by the CD4⁺ clones. A major role of CD4⁺ T cells specific for viral peptides associated with MHC class II glycoproteins on B cells is primarily the generation of ‘helper’ cytokines such as interleukin 4 (IL-4) and IL-5. These cytokines promote the clonal expansion and differentiation of B cells to antibody-secreting plasma cells.

The inflammatory exudate that can be lavaged from the respiratory tract of mice with influenza is dominated by macrophages, natural killer (NK) cells and T lymphocytes, with the CD8⁺ subset being 2–3 times more prevalent than the CD4⁺ cells. Macrophage recruitment and activation occurs in the absence of the CD4⁺ population and is dependent on nonspecific chemokine/cytokine recruitment probably produced from infected respiratory epithelia. The number of T cells in the exudate declines rapidly from the time that it is no longer possible to recover infectious virus. A role for NK cells in mediation of virus clearance has not been well established. Major questions concerning the nature of influenza pneumonia include the relative roles of different lymphokines, cytokines and chemokines in the disease process.

T cell specificity and memory

Infection with any influenza A virus primes for a secondary CD8⁺ T cell response to any other influenza A virus. This reflects that many of the CD8⁺ T cells are specific for peptides of conserved, internal virus proteins presented on the cell surface in the binding site of self MHC class I molecules. The NP is particularly prominent in this regard, though the M protein, nonstructural protein (NS1), and even the viral polymerases (PA, PB1-2) may contribute to antigenicity. The significance of a particular viral peptide depends on whether or not it binds to the MHC class I glycoproteins expressed in the individual at risk. Presence of these cross-reactive memory T cells has been correlated with less severe disease and their absence is probably the reason why influenza tends to be more lethal in very young children and in the elderly. Mouse experiments using

limiting dilution analysis (LDA) suggest that following infection, increased numbers of CD4⁺ or CD8⁺ T cells persist in lymphoid tissue for life. CD8⁺ T cell clonotypes that survive in the long term have virus-specific frequencies at least 30-times those found in naive animals, and express characteristic profiles of adhesion and activation antigens such as CD44 and CD62L. These cell surface molecules are believed to influence lymphocyte recirculation and homing.

Influenza-immune CD4⁺ helper T cells are specific for viral peptides presented in the context of self MHC class II glycoproteins. Following infection, the normal sequence of events is that antigenic determinants on the viral coat glycoproteins are bound by Ig receptors on appropriate B lymphocytes. This leads to the interiorization of the virus-Ig complex, degradation in lysosomes, and expression of constituent peptides + MHC class II molecules on the surface of the B cell. Lymphokines, such as IL-2 and IL-4, that are needed to promote the growth and differentiation of B lymphocytes specific for the influenza hemagglutinin (HA) molecule, can thus be provided by T helper cells reactive to epitopes derived from any of the viral proteins. This may be one reason why whole, inactivated influenza virus vaccines are more effective than, for instance, those consisting solely of HA subunits.

INNATE IMMUNITY

Edwin L Cooper, Laboratory of Comparative Immunology, Department of Neurobiology, School of Medicine, University of California, Los Angeles, California, USA

Innate, or natural, immunity includes all non-specific resistance or immune mechanisms, in contrast to *specific or acquired immunity* which exhibits exquisite antigen specificity and immunological memory (Figure 1).

History and nomenclature

Metchnikoff, toward the end of the nineteenth century, fully realized the capabilities of mononuclear phagocytes, and in a series of brilliant comparative and descriptive studies, he related the phagocytic function of metazoan amoebocytes to vertebrate macrophages. The applications of his work concerned host-defense reactions to infectious agents

and other materials that cause inflammation. Later, during the first quarter of the twentieth century, cytochemical procedures facilitated the recognition that phagocytic cells such as monocytes and macrophages were of widespread occurrence throughout the body. Three categories of mononuclear phagocytes have been defined: 1) those found circulating in the blood (monocytes); 2) those that are fixed in tissues and organs; and 3) those that move about or wander around in loose connective tissues. Much confusion has existed in terminology because of variations in organ localization and methods of study, multiplying synonyms for functionally related types. Simply defined, mononuclear phagocytes found in the peripheral blood derived from bone marrow are

Figure 1 Nonspecific innate immunity is a characteristic of all living animals, a universal defense system found in invertebrates and vertebrates. Phagocytosis and the activities of natural killer cells are inherent in this form of immunity. In contrast, specified adaptive immunity evolved and reached its most complex development in vertebrates including fish, amphibians, reptiles, birds and mammals.

monocytes. Once they leave the peripheral blood, we will refer to the more mature cells of the tissues as *macrophages*.

Nongranular leukocytes

Vertebrates, and many invertebrates, have evolved a system of internal transport for communicating between components of the immune system. This system comprises the blood and lymph within the circulatory and lymphatic systems. Blood contains two major types of cells: erythrocytes, or red blood cells, and leukocytes, or white blood cells. There are two basic types of leukocytes, nongranular and granular, which play important roles in the immune system. Nongranular (agranular) leukocytes are further divided into two types: *lymphocytes* and *monocytes*. Lymphocytes possess receptors for antigens on their surfaces and are thus vital to specific immune responses throughout the body. Like other blood cells, monocytes are produced in the bone marrow and then enter the blood system. They frequently exhibit ameboid movement, and become voracious phagocytes when they leave capillaries and enter connective tissues as macrophages. In adaptive immune responses, macrophages are involved in the presentation of antigens to T cells.

Granular leukocytes

Granular leukocytes include *neutrophils*, *eosinophils* and *basophils*. The number of neutrophils increases during infections to provide one of the first lines of defense against invading foreign material and microorganisms. In allergies and parasitic infestations, the number of eosinophils increases. Basophils are

important for the production of histamine, the primary cause of skin reactions in allergic responses. The most actively phagocytic of leukocytes are neutrophils and macrophages, a functional characteristic carried out mainly in connective tissue. Both cell types ingest foreign particles, bacteria and degenerating cells and fragments, and are thus crucial to the body's nonspecific immune reactions. Such responses involve rapid elimination of foreign material, often without the intervention of antibody.

Phagocytosis

Phagocytosis is the process of ingesting foreign material. Macrophages and neutrophils will engulf almost anything. To verify the presence of phagocytic cells one need only inject an animal with carbon particles; shortly after the phagocytes can be seen to be blackened and heavily engorged with the ingested particles. Phagocytosis contributes significantly to an animal's resistance to infectious organisms. When the macrophage engulfs antigen (e.g. foreign particles or infectious organisms) it is processed and then presented to lymphocytes, setting in motion a chain of events that begin a specific immune response.

Enzyme synthesis

Since the original description of macrophages in the nineteenth century, it has been known that the cytoplasmic granules of activated macrophages take up more of the dye neutral red than do those of nonactivated macrophages. Neutral red is a basic dye that is specific for the enzyme components of macrophage granules. Procedures in histochemistry, coupled with the more sophisticated techniques of electron microscopy, have revealed that acid phosphatase is abundant in the lysosomes of macrophages. These protein enzymes in lysosomes are actively synthesized by macrophages. After the fusion of a phagosome (which forms immediately after phagocytosis) with a lysosome, enzymes are discharged into the resulting phagolysosome. A residual body consisting of digested material is formed and is then extruded by exocytosis.

Synthesis of lipids

Macrophages play an important role in the synthesis of lipids through their involvement in the uptake, hydrolysis and esterification of cholesterol. Reduced phagocytic function may contribute to the lowered rate of cholesterol metabolism during aging. Macrophages are probably involved in the onset of atherosclerosis during the degradation and synthetic utiliz-

ation of cholesterol and other lipids. By using either ^3H , ^{14}C , or ^{32}P to label different lipids, it has been shown that when cholesterol, triglyceride and phospholipid are ingested simultaneously by macrophages of lymph nodes, cholesterol is removed more slowly than either of the other two lipid components. During lipid metabolism, peritoneal macrophages from rabbits can incorporate labeled acetate into cholesterol, and they can degrade cholesterol. Alveolar macrophages contain cholesterol esterase and lipase. Fatty acids and triglycerides are taken up and oxidized by rabbit peritoneal macrophages, which also show increased phospholipid synthesis during phagocytic activity. Since lipids constitute an important component of all cell membranes, the universal presence of lipids is crucial to effective cell functions such as phagocytosis.

Interferon production

Macrophages are an important source of interferon, especially in the lungs, a place vulnerable to countless viral infections. When tissues which are rich in macrophages (e.g. spleen and liver) are cultured *in vitro*, they synthesize interferon within 24 h, whereas tissues which are poor in macrophages (e.g. kidney and brain) produce negligible quantities of interferon within the same time period.

Natural killer cells

Natural killer (NK) cells are not clonally distributed, nor do they exhibit memory responses. They patrol the body looking for cells which have lost expression of major histocompatibility complex (MHC) class I molecules, e.g. cells infected with certain viruses and some types of tumor cells. If such cells are encountered, they are then killed by the NK cells.

INSULIN-DEPENDENT DIABETES MELLITUS, EXPERIMENTAL MODELS

Ji-Won Yoon and **Hee-Sook Jun**, Department of Microbiology and Infectious Diseases, Julia McFarlane Diabetes Research Centre, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada; Institute for Medical Science, Ajou University School of Medicine, Suwon, Korea

Type I diabetes, also known as insulin-dependent diabetes mellitus (IDDM), results from the destruction of insulin-producing pancreatic β cells, culminating in hypoinsulinemia and hyperglycemia. IDDM appears to be a disease of autoimmunity. Genetic susceptibility is believed to be a prerequisite for the development of IDDM and environmental factors, such as viruses, diet and toxins are also considered to

be involved in the clinical expression of this disease (Figure 1).

Animal models of human autoimmune IDDM, such as the BioBreeding (BB) rat and the nonobese diabetic (NOD) mouse, have enhanced our understanding of the pathogenic mechanisms of this disease. The spontaneously diabetic BB rat was discovered in 1974 in a colony of outbred Wistar rats

Figure 1 Etiology of IDDM. Genetic susceptibility appears to be prerequisite for most, if not all, cases of IDDM. Environmental factors influence the clinical expression of genetic susceptibility. Certain environmental factors, such as viruses and toxins, may act as primary injurious agents to pancreatic β cells, or as triggering agents for autoimmunity in humans and animals. Once β cell-specific autoantigens, macrophages, helper T cells and autoantigen-specific cytotoxic T lymphocytes (CTLs) are involved in the autoimmune process. In addition, free radicals and cytokines released from macrophages and T cells, and autoantigen-specific T effector cells synergistically destroy β cells.

at the BioBreeding Laboratories in Ottawa, Canada. The cumulative incidence of diabetes in DP-BB/Wor rats is greater than 80%. The pattern of disease in the DP-BB rat is, in many ways, similar to human IDDM, with the exception of the association of T cell lymphopenia with the DP-BB rat (Table 1). The NOD mouse was developed in the course of a breeding program to establish a cataract-prone subline (CTS) from a subline outbred ICR mouse at Shionogi Research Laboratories in Osaka, Japan in 1974. The diabetic syndrome observed in NOD mice is similar to that of humans and BB rats with the exception of the incidence of disease between the sexes (Table 1). In the NOD mouse there is a greater incidence of diabetes in females (70–80%) when compared to males (10–20%).

Cumulative evidence indicates that β cell autoantigens, macrophages, $CD4^+$ T cells, and $CD8^+$ T cells are involved in the pathogenesis of β cell-specific autoimmune IDDM in the BB rat and in the NOD mouse. Cytokines produced from immunocytes and oxygen free radicals also contribute to the destruction of β cells. In addition, chemical toxins and viruses induce a diabetes-like syndrome in animals. Various strategies have been employed to prevent insulinitis and diabetes in animal models. Most strategies are based on immune modulation or immune intervention in order to block the process of autoimmune β cell destruction at different stages.

Genetics

The development of IDDM is controlled by multiple susceptibility genes including a locus in the major histocompatibility complex (MHC). In the BB rat, diabetes susceptibility is strongly linked to genetic markers for the MHC and the inheritance of phenotypic markers, such as T lymphopenia. The class II region of the rat MHC is comprised of the RT1B and RT1D loci, homologous to mouse I-A and I-E regions, and flanked by RT1A, RT1E and RT1C class I loci. The RT1D locus is homologous to the human HLA-DR. The BB rat expresses the RT1A^u, RT1B^u and RT1D^u haplotypes. MHC-associated diabetes susceptibility genes map to the class II region on chromosome 20 and the MHC class II RT1^u haplotype is required for the expression of diabetes, but MHC class I molecules are not associated with the expression of diabetes. The sequences of the first external domains of RT1B and RT1D β chains in BB rats are different from the sequence of other rat or mouse class II genes. It is noteworthy that Lewis rats, which are not diabetes-prone, and BB rats both lack aspartic acid at position 57 of the class II β chain. This suggests that the allelic amino acid at this position in the BB rat may not serve as a disease marker and that there may be other unidentified class II allelic differences involved in the susceptibility of BB rats to IDDM. T cell receptor polymorphisms have

not been linked to diabetes in the BB rat. The development of diabetes in the BB rat also correlates with the inheritance of severe T cell lymphopenia and is attributed to a lack of T cells expressing the RT6 cell surface alloantigen. Lymphopenia segregates independently of the RT1 haplotype. While the development of diabetes in nonlymphopenic BB-derived rats has occurred in rare instances, no permanently nonlymphopenic strain of rat that develops spontaneous diabetes has been created. Therefore, it is likely that the severe lymphopenic phenotype of the BB rat, inherited in an autosomal recessive fashion, is not essential for the development of diabetes but increases the probability of its development. Recently, a lymphopenic gene (*lyp*) was mapped close to the neuropeptide Y (*Npy*) gene on chromosome 4.

Early genetic studies in mice revealed that the susceptibility of NOD mice to IDDM is also linked to the H2 complex and is inherited as a recessive trait. Later studies with H2 congenic strains of NOD mice revealed that susceptibility to IDDM by H2 (Idd-1) is not recessive, but rather a dominant trait with varying degrees of penetrance for the phenotypes of insulinitis and diabetes. The NOD mouse is unique in that its H2 complex encodes for novel I-A molecules ($A\alpha^d$ and unique $A\beta$) in which aspartic acid at position 57 of the β chain is replaced by serine. Also the NOD mouse lacks I-E expression. However, the mutated I-A^{g7} $A\beta$ gene, which encodes aspartate at position 57, reduces the incidence of diabetes but does not prevent insulinitis. Studies with nondiabetic

NOD transgenic mice expressing normal I-E or other I-A molecules revealed that the unique H2 complex of the NOD mouse plays a direct role in the mouse's susceptibility to IDDM, but by itself the H2 complex is not sufficient for the onset of diabetes. The CTS strain, which expresses the same MHC class II allele as NOD mice but a different MHC class I allele, does not develop diabetes, indicating that H2 linked genes (at class I or class II loci) in addition to class II genes may also contribute to disease development. Although 50% or more of the genetic risk is transmitted by Idd-1, susceptibility of the NOD mouse to IDDM is also determined by a large number of non-MHC-linked genes (Table 2). The Idd-2 gene is weakly linked to the *Thy1/Apoa1* cluster on chromosome 9. The Idd-3 diabetes susceptibility locus mapped near the interleukin 2 (IL-2) gene on chromosome 3 and is associated with both insulinitis and diabetes. Idd-10 on chromosome 3 is associated with the expression of a defective Fc receptor (*Fcgr1*) of IgG. Idd-4, which maps to chromosome 11, is associated with the early onset of IDDM and may influence the frequency of insulinitis and may control the progression of severe insulinitis to overt diabetes. The mouse inducible nitric oxide synthase (iNOS) gene *Nos 2* is a candidate for Idd-4. Idd-5 is linked to the IL-1 receptor and the *Lsh/Ity/Bcg* genes which control resistance to intracellular pathogens on chromosome 1. Also, Idd-5 is the most important gene affecting insulinitis after the H2 gene. Idd-6, which maps to chromosome 6, affects the incidence of diabetes, but not the frequency of insulinitis. Idd-7 and

Table 2 IDDM susceptibility loci identified in the NOD mouse

IDDM locus	Chromosome	NOD allele	Linkage	Candidate gene
Idd-1	17	Susceptible	H-2	<i>Ab, Ea</i>

Idd-14	13	Susceptible		
Idd-15	5	Susceptible		
Idd-16	17	Susceptible	H-2	<i>Tnfa</i>

Idd-8 are located on chromosome 7 and chromosome 14, respectively. Another diabetes susceptibility gene on chromosome 14 near *Tcra* (T cell receptor α chain gene) is Idd-12. Idd-9 and Idd-11 are both located on chromosome 4 and the locus of the Na^+/H^+ exchanger 1 (*Nhe1*) is a candidate gene for Idd-11. Idd-13 was identified as a resistance allele on chromosome 2, linked to the *Il1a* gene. Idd-14 and Idd-15 are located on chromosome 13 and chromosome 5, respectively. Recently Idd-16 was located adjacent to the Idd-1 region. The *Tnfa* gene is a candidate gene for Idd-16. Thus, a series of alleles at different loci, each necessary but not sufficient for the development of diabetes, underlie the susceptibility to diabetes (Table 2).

Islet pathology

The DP-BB rat and the NOD mouse have many features that make them advantageous models of human autoimmune diabetes (Table 1). These models develop diabetes spontaneously; their symptoms characterized by hyperglycemia, glucosuria, ketonuria, polyuria, polydipsia, weight loss and death if insulin is not administered. In the BB rat, mononuclear cell infiltration, known as insulitis, of the pancreatic islets usually occurs at an age of 60–120 days in both males and females and lymphocytes are scattered throughout the islets. In contrast, lymphocytes are detected in the peri-islets at 4 weeks of age in the NOD mouse and these mononuclear cells appear to migrate toward the islets as the NOD mouse matures. Diabetes develops at 120–200 days of age in the NOD mouse. Insulitis often precedes or accompanies the onset of hyperglycemia in these animal models.

The progressive and selective loss of pancreatic β cells is an important characteristic of IDDM. This destructive process excludes other islet cell types, such as alpha (α), delta (δ), and polypeptide-producing (pp) cells, leaving them intact. After the onset of hyperglycemia, the degree of mononuclear cell infiltration decreases and end-stage islets have few or no inflammatory cells. The islet infiltrates consist of macrophages, dendritic cells, CD4^+ T cells, CD8^+ T cells, natural killer (NK) cells, and, to a lesser extent, B cells. Among them, macrophages and dendritic cells are the primary infiltrates of the pancreatic islets.

Immunopathology

Humoral immunity

One of the most commonly reported immunological

abnormalities of humans and animals with autoimmune diabetes is the presence of autoantibodies in their sera, directed against pancreatic islet cell antigens. Anti-islet cell autoantibodies have been divided into two types: islet cell cytoplasmic antibodies (ICA) and islet cell surface antibodies (ICSA). Both ICAs and ICSAs have been detected in the NOD mouse, but ICAs have not been detected in the BB rat. Autoantibodies against bovine serum albumin (BSA) and insulin have been detected in the BB rat and the NOD mouse. The presence of anti-64 kDa glutamic acid decarboxylase (GAD) autoantibodies and anti-38 kDa autoantibodies have been detected in the sera of BB rats. Although autoantibodies directed against a 64 kDa autoantigen have been detected in the NOD mouse, the detection of anti-GAD autoantibodies in NOD sera is controversial. Also, autoantibodies directed against a 52 kDa protein, peripherin and heat shock protein have been detected in the NOD mouse. However, anti-37/40 kDa (tyrosine phosphatase/IA2) autoantibodies detected in human diabetic sera have not been detected in either the BB rat or the NOD mouse. It is believed that these islet cell autoantibodies are predictive markers rather than pathogens.

Cell-mediated immunity

The role of cell-mediated autoimmunity in the pathogenesis of IDDM has been extensively studied in animal models. Evidence exists that supports the hypothesis that macrophages and T cells are clearly involved in the destruction of β cells.

Macrophages The major populations of infiltrating cells during the early stage of insulitis appear to be macrophages and dendritic cells. The infiltration of these cells is followed by the invasion of T cells, B cells and NK cells. Treatment of BB rats and NOD mice with silica, known to be toxic to macrophages, results in the near complete prevention of the development of insulitis and diabetes, suggesting that macrophages play an important role in the initiation of insulitis. Inactivation of macrophages in NOD mice at an early age with a long-term treatment of silica prevents the development of β cell-specific effectors. However, late, short-term treatment of NOD mice with silica does not affect the destruction of β cells by pre-existing effectors. Concanavalin A (con A)-activated spleen cells prepared from long-term silica-treated BB rats do not induce insulitis and diabetes in BB neonates, whereas con A-activated spleen cells from untreated BB rats induce both insulitis and diabetes, indicating that the inactivation of macrophages results in the loss of ability of the splenocytes to adoptively transfer insulitis and diabetes.

Late, short-term silica administration to BB rats does not, however, alter the ability of the splenocytes to adoptively transfer insulinitis and diabetes after con A activation. Thus, macrophages appear to be essential for the development of β cell-specific cytotoxic effectors in the initial phase of insulinitis in NOD mice and BB rats.

T cells There is much evidence to indicate that T cell-mediated autoimmunity is involved in the destruction of β cells. Neonatal thymectomy prevents diabetes in the BB rat. The lymphocytes from diabetic BB rats transfer disease to young diabetes-prone BB rats. BB rats treated with monoclonal antibodies (OX19) directed against antigens expressed on the surface of all T cells do not develop diabetes. T cell lymphopenia, characterized by a reduced level of CD4⁺ T cells and a substantial decrease in the number of CD8⁺ T cells, is observed in the BB rat. In contrast, the BB rat exhibits a relative increase in the number of NK cells (OX19⁻/OX8⁻). The proliferative response of T cells to mitogens, such as con A, phytohemagglutinin (PHA), and the production of con A-induced IL-2, is greatly reduced in DP-BB rats. The expression of the RT6⁺ antigen, which is a marker of mature lymphocytes, is defective in the DP-BB rat. However, the mechanisms involved in T cell lymphopenia and the defective development of mature T cells are not known.

It is known that autoimmune β cell destruction is mediated by both CD4⁺ and CD8⁺ T cells in the NOD mouse. Neonatal thymectomy prevents IDDM in the NOD mouse and adoptive transfer studies using cloned and uncloned T cells show that both CD8⁺ and CD4⁺ T cell subsets are required for the transfer of diabetes in NOD mice, NOD athymic nude mice, and NOD severe combined immunodeficiency (SCID) mice. Islet cell-specific T cell clones have been isolated from insulinitic lesions and the splenocytes of both prediabetic and diabetic NOD mice. CD4⁺ islet-specific T cell clones accelerate the development of diabetes in young NOD mice and destroy islet grafts in CD8⁺ T cell-depleted diabetes-resistant mice. The BDC2.5/NOD transgenic mouse, which expresses the rearranged T cell receptor (TCR) α and β chain genes of a diabetogenic islet-specific CD4⁺ T cell clone (BDC2.5), exhibits an increased incidence of diabetes. In contrast, some reports have shown that the CD4⁺ T cell subset alone is not sufficient for the transfer of diabetes in NOD mice. As well as CD4⁺ T cell involvement in β cell destruction, experimental evidence reveals that CD8⁺ T cells play a role as effector cells in the destruction of β cells in the NOD mouse. CD8⁺ cytotoxic T cell clones (CTLs), isolated from the islets of

diabetic NOD mice, can destroy β cells *in vitro* and transfer diabetes *in vivo* with the help of CD4⁺ T cells. Transgenic mice (TCR β /NOD) with a TCR β rearrangement from a diabetogenic CD8⁺ T cell clone exhibited an accelerated onset of diabetes. In addition, a β cell-specific CD8⁺ CTL clone, which expresses CD28 and CD44, effects β cell damage without the assistance of CD4⁺ T cells. Furthermore, β cell-specific CD8⁺ cytotoxic T cells directly destroy β cells in association with MHC class I-restricted antigens in islet transplanted murine models. In conclusion, both CD4⁺ and CD8⁺ T cells are required for the development of spontaneous diabetes in NOD mice (not transgenic models). However, the specific roles that CD4⁺ and CD8⁺ cells play in diabetogenesis remain unclear.

T cell receptor Most CD4⁺CD8⁺ and CD4⁺CD8⁺ T cells express $\alpha\beta$ T cell receptors and recognize antigenic epitopes presented by MHC class II and class I molecules, respectively. The great majority of CD4⁺CD8⁺ T cells express a TCR composed of γ and δ chains. Studies with T cells from NOD mice exhibiting insulinitis and islet-reactive T cell clones suggest a diverse TCR repertoire. Thus, the TCR repertoire of islet-infiltrating T cells in NOD mice is known to be polyclonal. However, the TCR-V β repertoire of islet-infiltrating T cells in very young NOD mice (2 weeks old) exhibits a monoclonal TCR-V β 8.2, suggesting that IDDM in NOD mice may be initiated by the recognition of a single autoantigen.

Collaboration of macrophages with CD4⁺ and CD8⁺ T cells in the destruction of β cells Macrophages, CD4⁺ T cells, and CD8⁺ T cells are involved in the destruction of β cells in NOD mice and BB rats. The interactions among these cells, however, are not well understood. Many studies indicate that macrophages are one of the first cell types to infiltrate the pancreatic islets. These cells must be involved in the pathogenesis of IDDM early on, since inactivation of macrophages results in the near complete prevention of insulinitis and diabetes in both NOD mice and BB rats. One of the key functions of the macrophage is the MHC class II-restricted presentation of processed antigen to helper T cells. Thus, it is reasonable to speculate that prior to the development of insulinitis, there may be antigenic changes on the β cell which are recognized as 'nonself'. Also, it is speculated that β cell autoantigens are released by the spontaneous turnover of β cells, or damage to the β cells by environmental factors (such as viral infection) resulting in their processing and presentation by macrophages. Thus, the presentation of β cell-specific autoantigens by macrophages to CD4⁺

helper T cells might be the initial step in the development of autoimmune diabetes (Figure 2). During this process, the activated macrophages secrete interleukin (IL)-12, IL-1 β , and other cytokines. IL-12 activates T_H1-type CD4⁺ T cells which, in turn, secrete interferon γ (IFN γ) and IL-2 (Figure 2). The secretion of IFN γ generates cytotoxic macrophages from resting macrophages. These cytotoxic macrophages secrete IL-1 β , tumor necrosis factor α (TNF α) and free radicals; substances known to be toxic to β cells. Simultaneously, IL-2 and other cytokines released from T_H1-type CD4⁺ T cells activate precytotoxic CD8⁺ T cells. These substances may also induce the migration of peripheral precytotoxic CD8⁺ T cells to the inflamed islets, perhaps by the induction and expression of specific homing recep-

tors on the endothelial cells. Precytotoxic CD8⁺ T cells bearing β cell antigen-specific receptors may differentiate into CD8⁺ cytotoxic effector T cells upon recognition of β cell-specific peptides bound to MHC class I molecules. Cytotoxic CD8⁺ T cells then effect β cell damage by the release of perforin and granzyme after recognition of MHC class I/peptide complexes on the surface of β cells. The Fas-FasL interaction appears also to be involved in the destruction of β cells. β cell-reactive CD8⁺ T cells may not have the ability to migrate to the pancreatic islets or to effect β cell damage in the absence of T_H1-type CD4⁺ T cells and macrophages. In this way, activated macrophages, T_H1-type CD4⁺ T cells, and β cell-specific CD8⁺ T cells synergistically destroy β cells in association with β cell-specific autoantigens

Figure 2 Schematic representation of the development of β cell-specific autoimmune IDDM. β cell autoantigens released from the β cells during spontaneous turnover or insult by viral infection are processed by macrophages and presented to helper T cells in association with MHC class II molecules. Macrophages release IL-12, which activates T_H1-type CD4⁺ T cells. While this process is taking place, β cell-specific precytotoxic T cells may be recruited to the islets. These precytotoxic T cells may be induced by IL-2 and other cytokines released by CD4⁺ helper T cells to differentiate into effector T cells. IFN γ released by helper T cells may cause macrophages to become cytotoxic. These cytotoxic macrophages release substantial amounts of β cell-toxic cytokines (including IL-1 β , TNF α , and IFN γ) and free radicals. In addition, the helper T cells secrete interleukins that activate other helper T cells, B lymphocytes, and cytotoxic T cells. The autoantigen-specific CD8⁺ cytotoxic T cells, as final effectors, may recognize the autoantigens expressed on many unaffected β cells, in association with MHC class I molecules. These CTLs release granzyme and cytolysin (perforin), which are toxic to β cells. In addition, Fas-mediated apoptosis is involved in β cell destruction. In this way, macrophages, T cells, and cytokines synergistically destroy β cells, resulting in the development of autoimmune IDDM.

and MHC class I and class II molecules, resulting in the development of autoimmune IDDM (Figure 2).

Cytokines

Biochemical mediators of cytotoxicity, such as cytokines, perforins and proteases, may destroy β cells. Macrophage-mediated β cell damage is caused by cytokines, such as IL-1 β , TNF α , and IFN γ released from activated macrophages. IL-1 is selectively cytotoxic to pancreatic β cells *in vitro*. IL-1 β , TNF α , lymphotoxin and IFN γ act alone or synergistically to damage isolated islets or cultured islet cells. IL-1 β -stimulated and TNF α -stimulated endogenous iNOS activity is revealed as a major source of β cell injury. These cytokines are expressed in the insulinitic lesions of NOD mice and BB rats. Monoclonal antibody directed against IFN γ prevents the development of diabetes in these animal models. Transgenic expression of IFN γ in the β cells of normal mice results in the autoimmune destruction of β cells and the development of IDDM.

The genetic absence of IFN γ in NOD mice, inactivated by a mutation in the IFN γ gene, results in a significant delay of the development of diabetes. Transgenic expression of IFN α in the β cells also exhibits an immune-mediated destruction of islet β cells, and antibody against IFN α prevents β cell damage and IDDM in these transgenic mice. In general, T_H1-like cytokines, such as IL-2 and IFN γ , are β cell destructive, while T_H2-like cytokines, such as IL-4 and IL-10, are preventive although the local expression of IL-10 accelerates the development of diabetes. The administration of IL-12, a cytokine that is thought to play a key role in the promotion of T_H1 immune responses to NOD mice, accelerates the onset of diabetes. It was reported that IL-12 mRNA expression was elevated in prediabetic DP-BB rat islets and that this cytokine is associated with the rapid development of diabetes in NOD mice. Thus, it is likely that cytokines play an important role in the destruction of β cells. However, the precise mechanisms whereby cytokines effect the destruction of β cells remain to be determined.

Free radicals

The generation of oxygen free radicals in target cells has been implicated as one of the various mechanisms involved in the destruction of β cells. The β cell is very sensitive to the production of free radicals because islet cells exhibit very low free radical scavenging activities. The cytokines IL-1 β , TNF α , and IFN γ are known to induce iNOS, which in turn generates the free radical nitric oxide (NO) from L-arginine. NO exerts a toxic effect on β cells by inhibiting iron-dependent enzymes, thereby impairing cellular

mitochondrial function and DNA synthesis. NO is also capable of generating cytotoxic hydroxyl radicals. Islets with advanced infiltration highly express iNOS, suggesting that expression of iNOS may be associated with the development of diabetes in BB rats and NOD mice. Thus it appears that free radicals, such as NO (generated by iNOS), may contribute to β cell destruction.

Environmental factors

Susceptibility to IDDM is determined by genetic factors; however, the concordance rate for IDDM between monozygotic twins approaches only about 35%, suggesting that as well as genetic factors, non-genetic environmental factors influence the clinical expression of this disease. Viruses, toxins, diet and stress have all been implicated as possible environmental determinants of IDDM.

Viruses

There are at least two different mechanisms by which viruses cause IDDM. One mechanism involves the direct infection of β cells and virus replication within them, resulting in their lysis. The best-studied model of virus-induced IDDM is the encephalomyocarditis (EMC) virus-induced animal model in which the EMC virus acts as the primary injurious agent to β cells. Susceptibility to EMC virus-induced diabetes is controlled by genetically determined host factors. The involvement of T cells in the destruction of β cells in EMC-M-infected mice was suggested in early studies; however, later studies using EMC-D virus-infected animals did not support T cell-mediated involvement. Recent studies reveal that macrophages play a critical role in the process of β cell destruction soon after EMC-D virus infection. The development of EMC-D virus-induced diabetes is controlled by a single gene of the host and a single amino acid of the polyprotein of the virus.

The other mechanism for virus-induced diabetes involves the triggering of β cell-specific autoimmunity, leading to the autoimmune destruction of β cells. Kilham rat virus (KRV) causes autoimmune diabetes in DR-BB rats without the distinct infection of β cells. Since KRV widely infects peripancreatic and other lymphoid tissue, but not pancreatic β cells, it has been suggested that KRV triggers autoimmune diabetes by perturbing the immune system of genetically predisposed DR-BB rats, although the exact role KRV plays in the induction of diabetes in DR-BB rats is not known.

In addition, coxsackievirus B4 induces diabetes in mice and produces transient diabetes in nonhuman primates. It is suspected that bovine viral diarrhea

mucosal disease virus causes IDDM in cattle. When neonatal golden Syrian hamsters are infected with β cell-passaged rubella virus they develop diabetes. β cell-specific expression of endogenous retrovirus is associated with the development of insulinitis and diabetes in NOD mice. It was also demonstrated that reovirus causes autoimmune IDDM in mice. Transgenic mice expressing lymphocytic choriomeningitis virus (LCMV) glycoprotein (gp), or influenza virus hemagglutinin in the β cells have been developed in order to investigate the potential association between viruses and IDDM. Young hosts that express LCMV glycoprotein in their β cells develop diabetes when they are exposed to the same virus later in life. Transgenic mice that express influenza virus hemagglutinin in their β cells develop autoimmune diabetes. In contrast to the induction of diabetes, LCMV and mouse hepatitis virus (MHV) prevents the development of autoimmune IDDM in the BB rat and the NOD mouse.

Toxins

Diabetogenic chemicals such as alloxan, streptozocin (STZ), chlorozotocin, vacor and cyproheptadine may destroy β cells by several different mechanisms. These chemicals may generate oxygen free radicals and alter endogenous scavengers of these reactive species. By breaking DNA, these chemicals may also increase the activity of the enzyme that depletes nicotinamide adenine dinucleotide poly-ADP ribose synthetase in β cells and they may inhibit active calcium transport and calmodulin-activated protein kinase activity. One high dose of STZ causes complete β cell necrosis and the onset of diabetes within 24 h in dogs, hamsters, monkeys, mice, guinea pigs, and many species of rats. Multiple subdiabetogenic doses of STZ produce pancreatic insulinitis, progressing to overt diabetes in certain inbred strains of mice. An autoimmune mechanism may be involved in the onset of diabetes after multiple low doses of STZ since antilymphocyte serum plus 3-O-methylglucose, prior to STZ treatment, prevented the onset of diabetes. Also, athymic nude mice were resistant to STZ-induced diabetes. It has been suggested that IFN γ plays a role in the induction of diabetes in this model. However, it was reported recently that STZ induces diabetes in NOD-SCID mice, suggesting another mechanism is involved. In addition, type C retrovirus particles have been found in the β cells of animals with STZ-induced diabetes.

Diet

Diet may alter metabolism, cellular structure and function, as well as the immune system. It has been shown that food diabetogens affect the expression of

the diabetic syndrome in BB rats and NOD mice. The source of dietary protein seems to be the most important factor and intact protein may be required for expression of genetic susceptibility to diabetes in BB rats. Wheat gluten, soybean meal, alfalfa and skim milk powder have been identified as the most likely sources of dietary diabetogens in rodents.

Prevention

There are a number of immunotherapeutic interventions that can delay or prevent autoimmune destruction of pancreatic β cells. Neonatal thymectomy, which prevents the generation of mature T lymphocyte populations, prevents IDDM in BB rats and NOD mice. Treatment of animals with antibodies directed against T lymphocytes or T lymphocyte subsets (CD4⁺ T cells or CD8⁺ T cells) has been reported to prevent diabetes in BB rats, NOD mice and the STZ-induced diabetes animal model. Depletion of macrophages by the administration of silica also prevents diabetes in BB rats and NOD mice.

Immunosuppressive agents, such as cyclosporine, FK506 and rapamycin prevent insulinitis and diabetes in NOD mice and BB rats. Paradoxically, it has been reported that immune stimulation prevents IDDM. In NOD mice, OK-432 (streptococcal product), the fungal polypeptide IZ-8, BCG, complete Freund's adjuvant (CFA), and certain staphylococcal enterotoxins prevent diabetes. In addition, the systemic administration of cytokines, such as IL-4 and IL-10, protects β cells from autoimmune destruction in NOD mice. TGF β , secreted from suppressor T cells, prevents the development of diabetes in NOD mice. Some T cell clones isolated from NOD mice also prevent diabetes.

Blocking β cell-specific cytotoxic activity produced by free radicals with antioxidants also prevents diabetes. Activated macrophages and cytokines produced by immunocytes that have infiltrated the pancreatic islets contribute to β cell destruction by a process that generates free radicals, such as NO. The administration of antioxidants such as nicotinamide, vitamin E, probucol, MDL 29311, and U78518F has been reported to prevent or delay the development of diabetes. The induction of immune tolerance by immunization with islet antigens, such as GAD, heat shock protein and insulin is another useful method for the prevention of diabetes. Intrathymic or intravenous injection or intranasal administration of GAD protein to young NOD mice prevents insulinitis and diabetes. The administration of insulin reduces the incidence of insulinitis and diabetes in both NOD mice and BB rats.

Conclusion

The mechanisms responsible for the development of IDDM are multifactorial; thus, the simplification of these pathogenic mechanisms is not easy. Both genetic and environmental factors are involved in the development of autoimmune IDDM. β cell autoantigens, macrophages, T cells and immunocyte-derived soluble mediators, such as cytokines and oxygen free radicals, synergistically destroy β cells, resulting in the development of clinical IDDM. The control of pathogenic processes may depend upon the delicate balance of immunoregulatory T cells and/or their secreted cytokines. Animal models of IDDM, such as the BB rat and the NOD mouse, have greatly enhanced our understanding of the role that macrophages and T cells, as well as their soluble mediators, play in the pathogenesis of autoimmune IDDM. Although these animal models are not identical to human autoimmune IDDM, the knowledge gained from their use is invaluable for understanding the pathogenic mechanisms of human autoimmune IDDM and for the development of immunological methods for the prevention of this disease in humans, since there are extraordinary similarities between animal and human systems at the clinical, pathological and immunopathological levels.

INSULIN-DEPENDENT DIABETES MELLITUS, HUMAN

Andrew Muir and **Noel Maclaren**, Department of Pathology and Laboratory Medicine, University of Florida College of Medicine, Gainesville, Florida, USA

Contemporary management of insulin-dependent diabetes mellitus (IDDM) is intrusive and cannot guarantee complication-free survival. Improved understanding of the pathogenesis of IDDM has, however, provided optimism that this autoimmune disease will soon become either preventable or curable. While determined by multiple genes, the predisposition to destruction of the insulin-producing β cells in the pancreatic islets of Langerhans is transmitted predominantly through the class II human leukocyte antigen (HLA) DR and DQ loci. These predispositions involve the failure of multiple regulatory mechanisms and breakdown of immunological tolerance to self, probably induced by exposure to one or more incompletely identified environmental triggers. Particular attention has focused on the identification of specific islet autoantigens, soluble mediators of cytotoxicity (e.g. cytokines, superoxides), the balance between antigen-specific CD4⁺ T_{H1} and T_{H2} cells, and the cytotoxic effects of macrophages and CD8⁺ T lymphocytes. Future treatments will focus on preservation of pancreatic β cells and/or provision of permanent and physiological insulin replacement.

Genetic predisposition

The risk for IDDM in a first-degree relative of a diagnosed patient exceeds by some 15-fold the 0.3% disease prevalence observed in the general population, documenting the complex genetic predisposition (Table 1).

A hierarchy of autoantigen epitope affinities to the antigen binding cleft has been proposed to explain HLA-mediated IDDM susceptibility. Whether more tightly bound autoantigens aberrantly stimulate autoreactive lymphocytes or else fail to induce tolerance normally remains speculative. Two amino acids within the dimeric DQ antigen binding site, one on the α chain and the other on the β chain, have particularly important influences. A neutral amino acid (alanine, valine, serine) at amino acid 57 of the β chain is associated with susceptibility, whereas aspartic acid at this residue is protective. Arginine at position 52 of the DQ α chain occurs frequently in IDDM patients. If all four possible *cis*- and *trans*-encoded HLA-DQ α/β heterodimers comprise such

Table 1 Genetic influences of IDDM susceptibility

Relationship to proband	Risk for IDDM (%)
Parent	6

high-risk alleles, the patient is maximally susceptible. Transracial studies of IDDM susceptibility appeared to present data that conflicted with the Asp57 hypothesis. Blacks but not Caucasians with a DRB1*07;DQB1*0201 haplotype are susceptible. This may occur since the linked DQA chain (0501) in Blacks is the same as that found in Caucasians with the high-risk DRB1*03;DQB1*0201 haplotype. The DRB1*07 haplotype typically encodes a low risk DQA*0201 allele in Caucasians. Further, DQB1*0302;DQA*0501 is a susceptibility haplotype in Caucasians and Blacks, but not in Chinese or Japanese. This difference may arise from interactions between DR and DQ molecules. Indeed, DR β chains with aspartic acid at position 57 (DRB1*0403 or *0406) are protective even when present in HLA-haplotypes containing DQB1*0302;DQA*0301. Thus, susceptibility appears to arise mainly from DQ alleles, but it is influenced by HLA-DR and even LMP7, a locus within the haplotype that encodes part of the intracellular antigen processing complex.

Eleven other genetic intervals outside the HLA

Figure 1 Natural history of autoimmune IDDM. Islet autoimmunity is a multistage process that becomes symptomatic only in its very late stages. An environmental stimulus in people with an inherited predisposition to disease leads to an initial insult to β cells that is associated with the appearance of circulating autoantibodies. Some islet cell mass may be lost, but the process may be transient and perhaps even partially reversible. Small amounts of β cell loss are clinically insignificant, but some individuals suffer inexorable depletion of islet cell mass, causing symptomatic hyperglycemia (i.e. IDDM). The rate of islet loss may be slowed by the initiation of insulin therapy and this process may be decelerated further by adjunct therapies, such as immunosuppression. The goal of preventive therapies is to arrest the loss of islet cell mass. It is anticipated that the maximal success of such treatments will depend on their initiation early in the preclinical stages.

locus have been reported to affect IDDM susceptibility. While the discovery of more intervals is expected, only four of those found so far have been confirmed (Table 2). IDDM2 has been mapped to the variable number of tandem repeats (VNTR) locus, upstream of the insulin gene (INS). The region is thought to enhance insulin transcription, the high-risk allele being associated with higher levels of INS mRNA. Higher rates of preproinsulin transcription may result in enhanced autoantigen production in β cells. Interestingly, the 2–5-fold relative risk for IDDM conferred at IDDM2 is preferentially or solely transmitted through paternal alleles. This could be best explained by a maternal imprinting, an effect strongly observed for the adjacent IGF2 gene. Diabetic fathers are at least three times more likely to

have affected children than are diabetic mothers, consistent with a parentally-biased transmission of the INS alleles.

Environmental factors

Autoantibody evidence that the disease process has started begin finally during infancy or early childhood (Figure 1). The role of viral or dietary triggers of β cell autoimmunity have long been postulated, but not clearly identified. Proposed pathogenic mechanisms have included direct islet cell viral infection, resulting in either altered self molecules or release of previously sequestered antigens from damaged β -cells, and/or a superantigenic event. Alternatively, molecular mimicry between a viral or dietary protein antigen and an islet autoantigen may provide the inductive event.

Congenital rubella, the first proven viral mediator of IDDM, is associated with an onset of hyperglycemia during the first 5–20 years of life in some 12% of such patients. More recently, enteroviruses, particularly Coxsackie B4, have been proposed as disease precipitants. SJL/J mice became hyperglycemic after their infection with a Coxsackie virus that had been isolated from the pancreas of a child who died at IDDM onset. Conflicting retrospective analyses of enteroviral serology in children with new-onset IDDM have appeared both before and after this. Acute enteroviral infection during pregnancy, documented by IgM titers, was prospectively associated with a higher risk of IDDM in the offspring before age 3 years. A putative molecular mimic of the Coxsackie P2C protein has been suggested to exist on the β cell autoantigen, glutamic acid decarboxylase₆₅ (GAD₆₅). A superantigen effect was implicated in IDDM pathogenesis after a disproportionate representation of V β 7 T lymphocyte clones was found in the pancreas of two children who died at their onset of IDDM. However, the polymerase chain reaction methodology used to detect this is fraught with the potential for quantitative artifacts.

Epidemiologic studies have suggested a direct association between cow's milk ingestion during infancy and diabetes, whereas an inverse relationship has been observed between the disease and duration of breast feeding. Antibodies to both the albumin and the globulin fractions of milk have been variably reported at higher rates in new-onset IDDM patients than in healthy controls. Further support for the hypothesis has arisen in experimental animal models of IDDM, in which dietary replacement of bovine protein has reduced diabetes incidence. It has been suggested that the ICA-69 protein of islets is mimicked by a 17mer (ABBOSS) contained in bovine

Table 2 Confirmed genetic intervals mapping IDDM susceptibility

Interval designation	Chromosome map	Identified genes
IDDM1	6p21	HLA-DQ, HLA-DR
IDDM2	11p15	VNTR 5' of insulin
IDDM4	11q13	
IDDM5	6q24–25	
IDDM8	6q25–27	

serum albumin (BSA). ICA-69 however is a ubiquitous antigen and in some studies antibodies to the protein occur at equal frequencies among diabetic and healthy control subjects. Antibodies against ABBOSS, as well as peripheral blood T cell proliferation in response to it, have been reported but not independently confirmed. T cell responses to β -lactoglobulin have also been reported in 55% of new-onset IDDM patients compared with 22% of controls. Multicenter prospective trials of cow's milk withdrawal are planned to address definitively this important public health issue.

Islet cell autoantigens

Pancreatic β cell components that are recognized by autoantibodies include insulin, proinsulin, GAD₆₅, and two protein tyrosine phosphatases, insulinoma antigen-2 and -2 β (IA-2 and IA-2 β). Other islet antigens suggested include carboxypeptidase H, ICA-69 and GM gangliosides. Humoral reactivities against these antigens are not believed to be directly harmful; however, they have provided a valuable means of identifying patients whose pancreatic β cells are under autoimmune attack. Islet cell autoantibodies (ICAs) in serum of healthy individuals are identified by indirect immunofluorescence of frozen human pancreatic sections. They are the most sensitive single predictor of future IDDM because they represent composite antibody reactions to multiple antigens. Interpretation of ICA positivity requires knowledge of the titer, the presence of other autoantibodies, the age and genetic risk of the patient, and the ability of pancreatic β cells to produce insulin after an intravenous glucose stimulus. Importantly though, the predictability of a positive ICA result is the same for relatives of patients as it is for the general population. However, the ICA procedure is technically demanding and simpler procedures for detecting autoantibodies against defined autoantigens are more reproducible. In our experience, detection of autoantibodies to GAD₆₅ plus those to insulin and/or to IA-2 could substitute for ICAs without loss of sensitivity in predicting IDDM.

Insulin was the first defined autoantigen to be identified in IDDM. In radiobinding assays, IAA are highly predictive of IDDM when they coexist with ICAs in subjects under 10 years of age. In a 1991 report, autoantibodies to proinsulin were detected by radiobinding assay 50% more often than IAA in 97 new-onset diabetic subjects. A 13 amino acid T lymphocyte epitope in IDDM patients that spans the C peptide-B chain junction of the prohormone has been reported, the sequence of which is 70% homologous to a T cell epitope of GAD₆₅.

Absorption of ICA activity from the sera of some IDDM patients by preincubation with the recombinant GAD₆₅ has been demonstrated and autoantibodies against GAD₆₅ (GADAb) can now be detected by immunoassays that are sensitive, accurate and reproducible. GADAb are found in 75% of new-onset IDDM patients, one-third of whom test negative for ICAs. Most longstanding ICAs after disease onset are, in reality, GADAb. As predictors of future IDDM however, their value is reduced by their moderately high frequency in normal adults. When GADAb coexist with additional ICAs, however, they indicate a high risk of IDDM.

The membrane-associated protein tyrosine phosphatase, IA-2, is expressed in islets, brain and pituitary gland. Its sequence confirms that its truncated form is the target of the previously identified autoantibody called ICA-512. Some 60–75% of new-onset patients have autoantibodies against the protein, compared with only 2% of healthy controls. In addition, among IDDM patients who were prospectively identified before disease onset (true prediabetics), seroconversion to IA-2 positivity increased from 60% to a maximum frequency of 75% in the year or so prior to IDDM diagnosis. Intra-islet expression of a homologous protein, IA-2 β , is restricted to β cells and displays an autoreactivity that is generally a subset of IA-2-positive persons. Autoantibodies against 40 kDa and 37 kDa fragments of trypsin-treated islet preparations that are closely related to IDDM susceptibility recognize portions of the intracellular domains of IA-2 and IA-2 β respectively, whereas those of 64 kDa and 50 kDa are directed against GAD₆₅ (Table 3). It is important to note that risk of IDDM is confined to those with more than one type of autoantibody.

Cellular immunity

Cellular autoimmune cytotoxic T cell effectors deliver the lethal hit to the pancreatic β cells. Aberrant peripheral blood T lymphocyte responses

Table 3 Islet autoantibodies in children

Autoantibody	Approximate frequency (%)			
	General population	Relatives	Pre-IDDM	New-onset IDDM
ICA	0.6	3.6	75	80
IAA	0.7	2.4	30	50
GAD ₆₅	1.0	2.5	75	75
IA-2	2.0	3.0	60	75
IA-2 β	2.0	3.0	35	40

to specific islet autoantigens have however been notoriously difficult to demonstrate in humans. Thus, insights into possible defects of cellular immunity in IDDM have arisen from a handful of human studies and a large volume of work performed in experimental animal models. NOD mice and BB rats have been the most frequently used comparative models of spontaneous anti β cell autoimmunity. Islet inflammation or insulinitis is the hallmark lesion of IDDM. Mononuclear cells – initially macrophages and dendritic cells – accumulate around the islets. Subsequently, B and T lymphocytes (both $CD4^+/CD8^-$ and $CD4^-/CD8^+$) arrive and form a periinsulitis before the cells invade the islets. Lymphocyte invasion, unaccompanied by macrophages, has been suggested as resulting in a nondestructive insulitis. Limited studies of human islets obtained through autopsy material and pancreatic biopsies performed at the time of IDDM onset have demonstrated similar, but less dense mixed-cell infiltrates. The $CD8^+$ T lymphocytes are more prominent in human insulitis than in the lesions of the rodents. There is also a class I HLA hyperexpression that usually accompanies insulitis that may potentiate cell-mediated β cell destruction.

There is an inability to stimulate a syngeneic/autologous mixed lymphocyte reaction against self MHC in IDDM patients and in NOD mice, suggesting that antigen-presenting cell (APC)-dependent regulatory function may be defective. Intrathymic deletion of autoreactive T lymphocytes in NOD mice has also been shown to be defective. Whereas studies in the NOD mouse have demonstrated incomplete maturation of macrophages after exposure to colony-stimulating factor 1 (MSF-1) and interferon γ ($IFN\gamma$), similar effects have not yet been reported in humans.

$CD4^+$ T cells cloned from NOD mice can transfer diabetes to immunodeficient (SCID) recipients, but the process is greatly accelerated by co-infusion of $CD8^+$ cells. Recently, however, cloned $CD8^+$ cells have also been reported to transfer diabetes to naive recipients. The role of B lymphocytes in insulitis is undefined. Since neither insulitis nor diabetes can be transferred by B lymphocytes, they have been considered to have a nondestructive function in the insulitis lesion. However, a NOD μ heavy chain knockout mouse, which has normal T lymphocytes but no functioning B lymphocytes, did not develop insulitis. This suggests a possible regulatory role for these cells.

T lymphocyte clones, some recognizing either insulin or GAD₆₅, have been isolated from NOD mice. Whereas diabetes is transferred to recipients by injecting some of these clones, other clones actually

confer protection from the disease. Cytokine production by invading cells provides part of the explanation for these contrasting results. $CD4^+$ T_H1 -like cells that produce $IFN\gamma$ and interleukin 2 (IL-2) support the destructive processes of insulitis. In contrast, T_H2 -like cells that secrete IL-4 and IL-10 are more likely to inhibit the harmful actions of the T_H1 cells. Host genetics, the nature of the antigen, its route of entry, its affinity for the MHC-binding cleft, and accessory molecule interactions (e.g. B-7 on the APCs and CD28/CTLA4 on T lymphocytes) are among the variables determining whether immune reactions will be predominantly T_H1 or T_H2 . The pathogenesis of IDDM is, however, more complex than a simple T_H1 - T_H2 dichotomy. Production of soluble mediators of inflammation, including prostanooids, interleukins, chemoattractants and chemokines, exert both destructive effects on pancreatic β cells and regulatory actions on immune cells. Transient molecules, such as reactive oxygen species and nitric oxide, have also been implicated in β cell destruction.

Treatment

The mainstay of treatment for diabetes since the discovery of insulin in the 1920s has been hormone replacement and glucose level monitoring. Intensive insulin replacement has been made possible by the advent of home blood glucose monitoring (to replace urine testing) and the introduction of purified, recombinant insulins with variable kinetics (short, intermediate and long acting). Until β cells can be regenerated or replaced without triggering renewed autoimmunity, or until the autoimmune process can be arrested before critical depletion of β cells has occurred, a cure is unlikely.

Even with modern modes of insulin replacement, such as open-loop continuous subcutaneous insulin infusions, chronic complications of the disease persist at high rates. Closed-loop delivery systems, which include a glucose sensor and automated insulin delivery system (i.e. artificial pancreas), are not yet ready for routine clinical use. Engraftment of autologous, non- β cells, containing recombinant insulin-producing constructs, is unlikely to become a reality in the coming decade. Islet and pancreas transplantation has found a niche in clinical medicine for some long-term IDDM patients who are undergoing immunosuppression for coincident renal transplantation. Prolonged survival of grafts in the absence of immunosuppression has not, however, been consistently demonstrated, even in transplantation between identical twins. Encasement of isolated islets in inert capsules that are permeable to

soluble insulin and glucose (e.g. alginate) have attempted to subvert recrudescant autoimmunity. Unfortunately, these devices have been prone to structural breakdown and graft destruction.

Disease prevention has recently become the subject of clinical trials. Generalized immunosuppression with azathioprine/steroids or cyclosporine retards the progression of islet destruction but does not ultimately prevent it. Nonspecific immunostimulation with tuberculin antigen (PPD) or BCG and anti-inflammatory therapy with nicotinamide have not yet afforded the levels of protection in humans that were observed with much larger doses in NOD mice. Trials of daily subcutaneous injections of insulin in mice result in marked delays of onset and profound reductions of insulinitis. In a recent trial of the treatment in patients with late-onset autoimmune diabetes, improved C-peptide production and glycemic control compared with five ICA-positive controls receiving an oral hypoglycemic agent was seen. An ongoing multicenter US trial of daily subcutaneous insulin, the DPT-1, should have the statistical power to determine definitively whether such prophylactic therapy is efficacious. Our own NOD mouse studies have suggested that intentional immunization to autoantigens, such as insulin B-chains but not insulin A-chains, and the peptide AA 9-23 of the B-chains especially, may redirect immune responses towards those unassociated with harmful anti-islet cytotoxicity. Such an observation could be the starting point for a diabetes vaccine in man in the future. Similarly, the induction of immunological tolerance to autoantigens through oral administration has proven effective in experimental animal models of a number of autoimmune conditions, including IDDM. A trial to induce oral tolerance to insulin has therefore commenced as part of the DPT-1, and a companion study in newly diagnosed patients is also underway. A number of immunotherapies that have demonstrated efficacy in rodents await further study before human trials can be launched. These include long-acting cytokine therapy (e.g. IL-4 or IL-10) and infusion of soluble MHC-antigen complexes to anergize autoreactive T lymphocytes.

Conclusion

The autoimmune pathogenesis of IDDM has been established beyond any reasonable doubt. Specific emphasis must now be placed on unravelling the web of genetic influences, environmental triggers and immunoregulatory failures that conspire to cause pancreatic β cell depletion.

INTEGRINS

Nancy Hogg, Leukocyte Adhesion Laboratory, Imperial Cancer Research Fund, London, UK

In 1986 the term 'integrin' was proposed by Richard Hynes to describe a family of integral membrane receptors which promoted cell adhesion and communication through linking the intracellular activities of one cell with that of another cell or with the extracellular matrix. The integrins are now a superfamily of 22 receptors composed of noncovalently associated heterodimers of α and β subunits: 16 α and eight β subunits have been identified to date (Table 1). Leukocytes collectively express 13 of these 22 integrins but exclusively express only the six members of the β_2 - and β_7 -integrin families. The superfamily was previously subdivided into three main groups based on the sharing of a common β subunit (β_1 , β_2 or β_3) by α subunits of the very late activation (VLA) proteins, the leukocyte integrins (CD11/CD18 family) and the cytoadhesins, respectively. With the discovery of new integrins, it has become apparent that greater complexity exists. For example, the same α_4 subunit which binds to β_1 in VLA-4 can associate with a second β subunit, β_7 , and the α_v subunit of the vitronectin receptor (VNR) may unite with as many as five different β subunits. The cell-cell contacts formed by integrins are essential for many aspects of immune responsiveness, such as antigen presentation, leukocyte-mediated cytotoxicity and myeloid cell phagocytosis. Integrins are an essential part of an adhesion receptor cascade which guides leukocytes from the bloodstream across endothelium and into injured tissue in response to the chemotactic signals. The integrins expressed by leukocytes do not function constitutively but undergo a process of activation which is thought to involve changes both in integrin clustering and conformation, having the net effect of increasing the overall avidity of binding to ligand.

Structural relationships

α subunits

There is an overall 25% amino acid identity between the α subunits that increases to 45–63% between those which are from the same group. At the N-terminal end of the α subunits are seven homologous tandem repeated sequences (I–VII) of approximately 65 amino acids, of which three (V–VII) or four (IV–VII) contain putative divalent cation binding sites (Figure 1). Seven leukocyte integrins, including the four β_2 -integrins, VLA-1 ($\alpha_1\beta_1$), VLA-2 ($\alpha_2\beta_1$) and $\alpha_E\beta_7$ contain an extra 'inserted/interactive' or 'I' domain of ~200 amino acids located between repeated domains II and III. This domain belongs to the von Willebrand factor (vWF) protein family which is represented many times in nature in proteins involved in adhesion interactions. The crystallization of the Mac-1 and LFA-1 I domain in 1995 represented the first part of an integrin to yield to structural analysis. The I domain adopts a classic $\alpha\beta$ dinucleotide binding fold like the gp21 ras protein. Recently integrin domains I–VII have been modeled as a β -propeller domain resembling the β subunit of the same trimeric G protein complex.

β subunits

The eight β subunits share an overall 37–45% amino acid identity, with high homology in the cytoplasmic and transmembrane domains. The β_4 subunit, partnered by α_6 and found in hemidesmosomes, is distinctive in that it has a long cytoplasmic 'tail' of ~100 residues compared with the more typical ~45 residues found in the other β subunits. At the N-terminus of the β subunit extracellular domain there is

Table 1 The integrin α and β subunits and their characteristics

Family	β Sub-unit	α Sub-unit	CD group	$\alpha\beta$ Sub-unit	Receptor (R) name	Other name	Chromosome localization in humans	I region	Mol. wt (kDa) reduced	Ligand	RGD role	Distribution

C, collagen; Fb, fibrinogen; FN, fibronectin; L, laminin; LGL, large granular lymphocyte; Mph, macrophage; Neut, neutrophil; Thr, thrombospondin; TN, tenascin; VN, vitronectin; vWF, von Willebrand factor.

Figure 1 The domain structure of integrin heterodimers. The α and β subunits both contain the highlighted MIDAS (metal ion-dependent adhesion site) motif. Domains V–VII in I domain containing integrins (or IV–VII in others) have EF hand-like cation-binding sequences with a conserved motif DxDxDxxxDxxx (X is any amino acid). The positions of ligand-binding domains for ICAM-1 within $\alpha_4\beta_2$ are indicated as $////\Delta$. The β -subunit cytoplasmic domain insert shows the two conserved NPXY/F motifs present in all β subunits except β_4 and β_8 . The first NPXY motif has been shown to be important for affinity changes in β_1 and β_3 . The TTT motif in β_2 regulates adhesion through postreceptor events. TM, transmembrane sequence. (Reproduced with permission from Stewart *et al.* (1995).)

an area of high homology which is thought to participate in $\alpha\beta$ heterodimer formation and in ligand binding. Secondary structure prediction provides convincing evidence that this domain is homologous to the I domain of the α subunit, suggesting that seven integrins have two I domains, whereas the remainder have only the single I domain of the β subunit. More C terminal to this region, the β subunits have another distinctive feature in the positioning of 37 cysteines within a restricted area of 190 amino acids, giving rise to extensive disulfide bonding. Electron microscopic analysis of $\alpha_5\beta_1$ reveals a mushroom-shaped globular 'head', containing the ligand-binding area, supported on the membrane by 'stalks' formed by the C-terminal regions of the α subunit and the rigidly cross-linked β subunit.

Molecular aspects of ligand-binding metal ions and ligands

Integrins are metalloproteins and require divalent cations Mg^{2+} and Ca^{2+} for activity. In general the Mg^{2+} -bound integrin is functionally active, with the full role of Ca^{2+} still not completely understood. When agents such as phorbol esters are used to activate integrins, Ca^{2+} synergises with Mg^{2+} to increase integrin-mediated adhesion, whereas when integrins are directly activated with Mg^{2+} , adhesive activity is negatively regulated by Ca^{2+} . Potential metal-binding sites are located in the I domains of α and β subunits and the EF hand-like domains IV/V–VII of the α subunit. The I domains have an unusual Mg^{2+} -binding

site (Figure 1) termed the MIDAS (metal ion-dependent adhesion site) motif (DxSxS..T...D..). There is no definite information about which of these 4–5 sites are actually used during integrin activation.

The finding that the I domain of the α subunit contains a key ligand-binding site has stimulated much interest in ligand-binding areas of the α subunit. Elsewhere in the α subunit, ligand-binding sites are associated with the short repeating domains: V of GPIIb and domains V/VI of LFA-1 (Figure 1). Early experiments, in which RGD-containing peptides were cross-linked to the β_3 -integrins, indicated that approximately 80% of 'cross-linked' RGD bound to the common β_3 subunit within the highly conserved β 'I domain-like' sequence close to the MIDAS motif. Whether ligand can independently bind to these different sites or whether they come together to form a single 'maxi' binding pocket has still to be resolved. The concordance between ligand binding and cation binding suggests that cations might be directly part of the ligand-binding site or involved in conformational changes in association with the binding of ligand.

Ruoslahti and Pierschbacher showed that many but not all of the receptors which bind to matrix molecules recognise the tripeptide Arg-Gly-Asp (RGD). Another unusual feature of some integrins is their ability to bind to more than one ligand or counter-receptor. The VNR has the widest specificity, with binding activity for vitronectin, fibrinogen, vWF, fibronectin, thrombospondin and bone sialoprotein. In contrast, VLA-5 the classical fibronectin receptor, seems to bind only to fibronectin via recognition of the RGD sequence. VLA-3 and VLA-4 also recognize fibronectin, with the specificity of VLA-4 now known to be for another region of the fibronectin molecule, called the CS-1 domain. Further complexity arises from evidence that the same receptor isolated from two different cell types may have different binding specificities. For example, VLA-2 from platelets binds only collagen, but VLA-2 from endothelial cells binds both collagen and laminin. The ICAM-1, -2 and -3 recognised by the β_2 -integrin LFA-1 may serve as ligands in different situations: ICAM-3 is highly expressed by naive T cells and on antigen-presenting cells; ICAM-2 on endothelium; and ICAM-1 is widely induced by inflammatory stimuli and provides the most robust interaction with LFA-1.

Integrin function

β_2 -integrins

Integrins participate in cell interactions in many tissues, including those of the immune system. Of the

integrins specific to leukocytes, Mac-1 and p150,95 are largely confined to the cells of the myeloid lineage. These β_2 -integrins are present in cytoplasmic granules but are rapidly translocated to the membrane following exposure of myeloid cells to inflammatory stimuli such as cytokines and chemokines. Mac-1 has an impressive array of ligands, including iC3b, fibrinogen, factor X as well as ICAM-1, and the binding activities of p150,95 largely reflect that of Mac-1. Mac-1 is also found in *cis* associations with a number of surface receptors, including Fc γ RIIA, Fc γ RIIIB, urokinase and LPS/LBP-bound CD14, and it is proposed that Mac-1 may function as a transducer of signals resulting from the binding of these associated receptors to their ligands. Interestingly p150,95 also binds Fc γ RIIIB and LPS/LBP-bound CD14 and Petty and Todd have suggested that ligands may 'shuffle' between these two integrins during cell locomotion. The recently described $\alpha_D\beta_2$ is highly expressed by tissue macrophages and so far is the only β_2 -integrin to bind exclusively to ICAM-3.

In contrast, LFA-1 is found on all leukocytes. It functions in antigen presentation between T cells and different types of antigen-presenting cell where ICAM-3 may serve as an initial ligand; inhibition of T cell-mediated killing (but see next section); natural killer cell activity; neutrophil antibody-dependent cellular cytotoxicity; binding of tumor cells by activated macrophages and homotypic aggregation of proliferating leukocytes. The rapid response of memory T cells to antigen is facilitated by the presence of increased levels of LFA-1 and ligand ICAM-1, permitting enhanced cell-cell interactions. It is important to note that this increase in expression of adhesion receptors does not automatically cause elevated integrin activity. Triggering of T cells through specific receptors or with phorbol esters is necessary to bring about increased LFA-1 adhesion to ICAM-1. This control of receptor function through 'inside-out' signaling has the advantage that high avidity intercellular adhesion will occur only when the involved cells are activated. The increase in avidity is thought to depend on either redistribution of receptor in the membrane and/or conformational changes in LFA-1.

α_4 -integrins

The VLA antigens were first identified by Martin Hemler on T cells growing in long-term culture but are known to be more widely distributed. *In vivo* VLA-4 ($\alpha_4\beta_1$) is expressed on early thymic precursor cells and is retained until the 'double-positive' CD4⁺8⁺ blast stage prior to the exiting of functionally mature 'single-positive' CD4 or CD8 T cells

from the thymus into the circulation. Memory T cells and monocytes have enhanced levels of VLA-4, VLA-5 ($\alpha_5\beta_1$) and VLA-6 ($\alpha_6\beta_1$) and these receptors become activated like LFA-1 when these cells are triggered through the T cell receptor and are thought to function as the cells move within tissue compartments. The $\alpha_4\beta_7$ -integrin binds to fibronectin and VCAM-1 but is known as the mucosal homing receptor because it recognizes the mucosal addressin MADCAM-1. The second β_7 -integrin, $\alpha_E\beta_7$, is expressed by intraepithelial T cells and is the only integrin to recognize a member of the cadherin adhesion family, E-cadherin.

β_3 -integrins

The cytoadhesins (β_3 family) are also represented on leukocytes. The integrin gpIIb/IIIa is exclusively found on megakaryocytes and platelets and, by its binding to fibrinogen, functions as the key receptor on platelets in the clotting cascade. Fibrinogen binding by gpIIb/IIIa is tightly controlled; it occurs only after activation with agonists such as thrombin and involves a conformational change in gpIIb/IIIa (deduced from expression of ligand-induced binding site (LIBS) epitopes). Similar activation events permit gpIIb/IIIa to bind fibronectin or vWF, mediating the adhesion of platelets to endothelium or the subendothelial matrix. The other classical cytoadhesin, the VNR, is found on tissue culture-matured monocytes and is implicated in recognition of senescent or apoptotic leukocytes. This specialized form of phagocytosis ensures that dying cells are removed from tissues, limiting the damage caused by their potentially harmful contents.

Adhesion cascade

The cooperative action of integrins with the selectin adhesion receptors in successfully guiding leukocytes from the bloodstream across the endothelium and into injured tissue has been termed the adhesion cascade (Figure 2). It was initially thought that selectins alone were responsible for tethering leukocytes to stimulated endothelium but it is now recognized that the α_4 -integrins can also perform this role. In fact α_4 -integrins appear to be capable of participating in all stages of leukocyte transmigration, including leukocyte arrest on stimulated endothelium and movement across endothelium into the tissue space. LFA-1 and Mac-1 dominate as the integrins causing firm binding and cell flattening of cells on endothelium. Neutrophils rely only on LFA-1 and Mac-1 as they lack α_4 -integrins. Although chemokines are attractive candidates as integrin activators, more proof is needed that they are major activators of α_4 - or β_2 -integrins in this situation.

Integrin 'knockouts' in mouse and human

Many integrins have now been the target of gene deletion or 'knockout' (KO) experiments in mice. The majority of KOs are either embryonic or perinatal lethal, which indicates the importance of integrins in development. For example, the lethal α_4 KO characterized by the Hynes laboratory has confirmed a role for α_4 -integrins in muscle and neural crest development. Other approaches, such as inducible KOs or 'integrin null' chimeric mice, will allow exploration of the role of this integrin, which is of

Figure 2 Sequential interactions of a leukocyte with endothelium under the guidance of the 'adhesion cascade'. ICAM-1, intercellular adhesion molecule-1; LFA-1, lymphocyte function-associated molecule-1; MAdCAM-1, mucosal addressin cell adhesion molecule-1; VCAM-1, vascular cell adhesion molecule-1. (Reproduced with permission from Hogg N and Berlin C (1990) *Immunology Today* 16: 327–330.)

such importance in the adhesion cascade. On the other hand β_2 (CD18) KO mice have a normal phenotype but have severely depressed immune responses, e.g. reduced response to chemically induced peritonitis and also delay in transplant rejection. This analysis has become more specific with the characterization of the LFA-1 KO. These mice show the expected deficiencies when challenged in *in vitro* adhesion assays and also fail to mount an antitumor response *in vivo*, suggesting cell trafficking problems. Surprisingly, cytotoxic T lymphocyte responses toward common viruses are normal, indicating that LFA-1 may not always be necessary in the interaction between leukocytes and their targets.

The human 'KO' of the β_2 subunit or CD18, termed leukocyte adhesion deficiency (LAD), is a rare condition recognized in some 60 patients worldwide. Patients suffer from severe bacterial and fungal infections which arise from the inability of myeloid cells to perform phagocytosis and chemotaxis. In LAD, expression of three leukocyte integrins LFA-1, Mac-1 and p150,95, is reduced or absent owing to five types of genetic defect in the β_2 subunit, which prevents membrane expression of the $\alpha\beta$ complex. Another recognized integrin defect occurs in the equally rare Glanzmann's thrombasthenia, in which the expression of gpIIb/IIIa on platelets is reduced or absent due to mutations in the α subunit gpIIb.

INTERCELLULAR ADHESION MOLECULES: ICAM-1, ICAM-2 AND ICAM-3

Steven D Marlin and **Robert Rothlein**, Imperial Cancer Research Fund, Lincoln's Inn Fields, London, UK

The intercellular adhesion molecules ICAM-1 (CD54), ICAM-2 (CD102) and ICAM-3 (CD50) mediate a variety of critical intercellular adhesion events in the immune system through interactions with their counter-receptors, the β_2 -integrins LFA-1 (CD11a/CD18), Mac-1 (CD11b/CD18), p150,95 (CD11c/CD18), and speculatively, CD11d/CD18. The binding of members of the ICAM family with the β_2 -integrins physically stabilizes interactions between collaborating pairs of T and B cells, T cells

and antigen-presenting cells (APCs), and brings effector cells such as cytotoxic T lymphocytes (CTLs) and natural killer (NK) cells into close apposition with their target cells. In addition to promoting these intercellular collaborations, the binding of the ICAMs with the β_2 -integrins also plays a key role in leukocyte transendothelial migration during normal circulation and trafficking, and in the specialized localization of leukocytes in the vasculature and subsequent transendothelial migration into inflamed tissue.

All three ICAMs share a common polypeptide homology and structural motif, and the ability to bind LFA-1. The distinct functional role of each ICAM is dictated by their relative affinities for LFA-1 (ICAM-1 > ICAM-2 > ICAM-3), by differential binding to other β_2 -integrins (such as Mac-1 (CD11b/CD18)), their cellular distribution and regulation of expression, and differences in the ability to transduce costimulatory signals to lymphocytes (Table 1).

Expression and regulation

Overall, ICAM-1, ICAM-2 and ICAM-3 have complimentary patterns of expression and regulation which probably reflect different temporal and cellular roles in mediating leukocyte adhesion. ICAM-1 can be expressed on all leukocytes and a wide variety of nonhematopoietic cells, including endothelial and

epithelial cells. The expression of ICAM-1 is highly inducible and this appears to be a major mechanism of regulating ICAM-1 activity. Basal expression levels are typically low, but can be induced to much higher levels by inflammatory mediators such as interleukin 1 (IL-1), tumor necrosis factor (TNF), and interferon γ (IFN γ). Different mediators induce expression in different cells, and in combination may act additively or synergistically. On T cells, ICAM-1 expression is induced by activation. Typically, cell surface expression on activated or cytokine-induced cells can be detected within 4 h after induction, becomes maximal with 16–24 h, and remains high for some time thereafter. This inducible expression is usually the result of *de novo* transcription and translation, but mobilizable intracellular pools have been identified in monocytes. In addition to regulation through expression levels, some cells such as T lymphocytes may also regulate the net adhesive

activity of ICAM-1 by rapidly and transiently clustering the molecule at sites of cell-cell interaction.

In contrast to the inducible expression of ICAM-1 on activated cells, ICAM-2 and ICAM-3 are constitutively expressed on unactivated cells, and their cellular distribution is much more restricted. ICAM-2 is expressed on lymphocytes, monocytes, platelets and endothelial cells, but not on granulocytes. ICAM-3 is expressed on all leukocytes, but is absent from endothelial cells. The expression of ICAM-3 is most pronounced on cells capable of presenting antigen, including monocytes, resting lymphocytes, and dendritic cells.

Role in leukocyte adhesion

The role of the ICAMs in promoting adhesion between cells in the immune system has been demonstrated by a number of *in vitro* and *in vivo* approaches including functional inhibition with monoclonal antibodies, cell-binding experiments with purified proteins or transfected cells, and by mutagenesis. Experimental evidence suggests that together, ICAM-1, -2 and -3 can completely account for LFA-1-dependent adhesion. However, the distinct cellular distribution and expression patterns of the three molecules indicates that they are not just redundant systems, but rather serve different roles.

ICAM-1

ICAM-1 facilitates a variety of both afferent and efferent immune responses that require intercellular contact and collaboration, including T helper responses, T-dependent B cell responses, antigen-induced T cell proliferation, cell-mediated cytotoxicity, and the binding of leukocytes to vascular endothelium prior to extravasation into inflamed tissue. In these events, the binding of ICAM-1 to LFA-1 acts as an antigen-independent, generalized 'accessory' adhesion mechanism that holds cells in close proximity long enough for other receptor/ligand interactions (MHC/Ag receptor, cytokines, etc.) and cellular functions to take place.

The phenotypes of ICAM-1-deficient mice show that ICAM-1 is not essential for leukocyte development and maturation. However, these mice display impaired contact hypersensitivity, defective neutrophil migration, and their cells are defective stimulators of mixed lymphocyte responses. In addition, ICAM-1-deficient mice are resistant to septic shock induced by either superantigen or endotoxin, and this resistance appears to reflect defects in T cell activation by superantigen and decreased neutrophil infiltration into the liver stimulated by endotoxin.

In addition to its role in the immune system,

ICAM-1 has been subverted by some human pathogens for their own use; the major group of human rhinoviruses (causative agents of the common cold) use ICAM-1 as an obligate receptor for cell entry and infection, and red blood cells infected with the malarial parasite *Plasmodium falciparum* bind to ICAM-1 expressed on endothelial cells.

ICAM-2

In contrast to ICAM-1 and ICAM-3, the functional role of ICAM-2 is not clear. Although it is constitutively expressed on most leukocytes and platelets, it is most strongly expressed on normal endothelial cells, and its expression is not modulated by inflammatory cytokines. ICAM-2 may thus serve a role in mediating the normal recirculation of LFA-1⁺ lymphocytes in the absence of an inflammatory or immune response. Acting in concert with ICAM-1, ICAM-2 may also help to trigger further adhesion strengthening and transendothelial migration by inducing an increase in the avidity of LFA-1 for all of the ICAMs. Combinations of anti-ICAM-2 and anti-ICAM-3 antibodies inhibit the mixed lymphocyte reaction (MLR), suggesting that ICAM-2, like ICAM-3, may help to initiate immune responses. Finally, ICAM-2 is the only known β_2 -integrin ligand on platelets, which suggests that it might play a role in leukocyte-platelet interactions.

ICAM-3

The constitutive expression of ICAM-3 and its restricted distribution on resting lymphocytes and antigen-presenting cells indicate that its major role is in facilitating intercellular adhesion in the initiation of immune responses, and indeed, ICAM-3 accounts for most of the functional LFA-1-dependent adhesion of resting T cells. Furthermore, the binding of purified ICAM-3 to LFA-1 delivers costimulatory signals to both resting and activated T cells, and as noted below, ICAM-3 may also transduce signals itself after receptor binding and cross-linking. The combined adhesion and signal transduction properties of ICAM-3 indicates that it plays an essential role in the initial stages of T cell-dependent immune responses.

Signal transduction

Optimal activation of lymphocytes through specific receptors such as the CD3/TCR complex requires additional receptor-ligand interactions that generate 'costimulatory' signals. The binding of each of the ICAMs to LFA-1 has been shown to provide some form of costimulatory signal to T cells. In addition,

ICAM-1 and ICAM-3 appear to be capable of direct signal transduction; cross-linking with certain anti-ICAM-1 or ICAM-3 antibodies can provide costimulation for T cell proliferation, and can induce intracellular Ca^{2+} mobilization and the phosphorylation of cellular proteins. Cross-linking of ICAM-1 costimulates the formyl-Met-Leu-Phe-induced oxidative burst in mononuclear cells, and cross-linking of specific epitopes on ICAM-3 induces enhanced LFA-1-dependent intercellular adhesion. Overall, the ability of ICAMs to provide costimulatory or accessory signals directly, or via LFA-1, is consistent with their role as adhesion and accessory molecules.

Structure and relationship to function

All three ICAMs are typical integral membrane glycoproteins and are members of the immunoglobulin gene superfamily base on sequence homology. The extracellular domains are composed of discrete immunoglobulin (Ig) domains of the C2 type comprised of seven antiparallel β strands which form two β sheets held together by at least one intradomain disulfide bond. The extracellular domains of both ICAM-1 and ICAM-3 contain five Ig domains, while ICAM-2 contains only two. The Ig domains are predicted to provide a stable, rigid structural framework, and electron microscopy of purified molecules shows that ICAM-1 and ICAM-3 are rod-shape molecules approximately 19 and 15 nm long, respectively. These dimensions are consistent with an end-to-end arrangement of the Ig domains. ICAM-1 has a characteristic bend between domains D3 and D4 that may represent an area of molecular flexibility that provides increased receptor accessibility to key binding sites located at the N-terminus. In both the native membrane-bound and shed forms, ICAM-1 can exist as a homodimer which has significantly greater binding to LFA-1 than the monomeric form.

Site-specific mutagenesis and domain deletion analyses have localized the receptor-binding sites on each ICAM. For binding to LFA-1, the primary site of contact appears to be the N-terminal domain (D1) on each molecule, with some contribution from the penultimate domain D2. The binding site on ICAM-1 for human rhinoviruses is also located in domain D1, perhaps reflecting the overall molecular accessibility of this domain as it is held above the cell mem-

brane by the rigid framework of the other Ig domains. In contrast, the binding site for Mac-1 on ICAM-1 is localized on domain D3, raising the possibility that LFA-1 and Mac-1 might bind simultaneously, or independently in a regulated manner.

In 1957 Isaacs and Lindenmann discovered that supernatants from virus-infected cell cultures contained a substance that could react with other cells to render them resistant to infection by the same or unrelated viruses. They named it interferon (IFN), which turned out to be a family of molecules all of which to some degree are able to interfere with viral infection. Moreover, IFNs are part of a superfamily of small proteins known as cytokines, that carry signals locally from one cell to another to play an important role in the body's natural defense system. In this respect, IFNs are considered to be the first line of defense against viral infection.

Although IFNs were first recognized for their potent antiviral properties, they were also shown to inhibit cell growth and promote differentiation. In addition, IFNs modulate the activity of virtually every component of the immune system including the antibody response, stimulation of cytotoxic lymphocytes, expression of major histocompatibility complex (MHC) and other surface antigens, recruitment of natural killer (NK) cells and activation of macrophages. Recently, one form of IFN has been implicated as playing an essential role in early pregnancy in several species of animals.

The IFNs have been classified into two types on the basis of their biological and physical properties. IFN α and IFN β are type I IFNs; IFN γ is a type II IFN. Type I IFNs can be produced by many cell types and induced by many substances, but the amount produced and the subspecies induced can vary per cell type and per inducer. Viruses and synthetic double-stranded RNAs are amongst the best inducers. Type II IFN is largely produced by T lymphocytes stimulated by foreign antigens or mitogens and by NK cells in response to viral infection. In general, type I IFNs are more potent inducers of viral resistance in cells while type II IFN is a better modulator of the immune system.

To elicit their biological properties, it is necessary that the IFNs bind to specific receptors on the target cells. The interaction of IFNs with their cognate receptors activates signaling pathways in which cytoplasmic activated transcription factors translocate to the nucleus and stimulate the induction of a set of primary genes which are central in mediating the biological response. This transcriptional activation is rapid and does not require protein synthesis. Similar

genetic activation of cells by IFNs appears to be required for most of its biological actions (e.g. antiviral, cell growth inhibitory and immunomodulatory activities).

The IFN α / β family

In all mammalian species studied, the α IFNs are encoded by a family of closely related genes. In the human genome at least 14 active IFN α genes and 4 pseudogenes can be discriminated. In addition, in the human genome a subfamily of IFN α -related genes, called IFN ω genes, have been identified. The IFN ω genes exhibit approximately 70% sequence homology with the other human IFN α genes and are mainly pseudogenes. In the mouse genome, 12 different complete IFN α genes have been isolated and characterized. Eleven of these encode biologically active proteins, the other is a pseudogene. The IFN ω genes appear to be absent in mice. Multiple functional IFN ω genes have been described in cattle, horse and sheep. Recently, it was shown that the IFN α genes are also present in birds; the chicken genome as well as the duck genome contain at least 20 IFN α genes. Human IFN β is encoded by a single copy gene, which exhibits approximately 40% homology at the nucleotide level to the IFN α genes, and which is physically closely associated with the IFN α gene family. The mouse genome, in common with human, possesses a single IFN β gene, whereas cattle, sheep and pigs possess multiple IFN β genes.

In humans, type I IFN genes are located within the band p22 on the short arm of chromosome 9. Recently, the first complete physical map of the type I IFN gene cluster has been established. In mouse, type I IFN genes are clustered on chromosome 4; in hamster on chromosome 2q.

In all mammalian species studied, type I IFN genes are devoid of introns and encode proteins of 186–190 amino acids, including a signal peptide of 23 amino acids. The IFN ω proteins, which have approximately 60% sequence similarity to the IFN α s, contain a C-terminal extension of 6 amino acids. All IFN α s contain four cysteine residues (positions 1, 29, 99 and 139) which are involved in disulfide bridges. An additional cysteine at position 86 is present in all murine, hamster and rat, and in

some human subspecies. Most murine and a few human IFN α subspecies contain an N-glycosylation site at position 78, and were shown to be glycosylated. The function of this glycosylation site is not understood, but it is not necessary for the biological activity of IFNs.

It is assumed that type I IFN genes share a common ancestor and that the IFN α gene family arose by repeated duplications of the ancestral α gene. The IFN α genes are relatively well conserved. Within a species the homology between the proteins is 70% or more. Between human and murine IFN α proteins the homology is 50–60%. Despite these structural similarities, IFN α s are relatively species-specific: most human IFNs have only a low activity on mouse cells. However, certain mouse IFN α s reveal high antiviral activity on hamster cells. Similarly, some hamster IFN α s show antiviral activity on mouse cells.

In response to developmental stimuli, trophoblasts of ruminants and humans secrete a distinct class of IFNs, IFN τ or trophoblast IFNs, which are involved in regulating maternal recognition of pregnancy. Several IFN τ genes have been identified in sheep and cattle and more recently in humans. Structurally, the amino acid sequence of IFN τ shows 30–70% homology to the type I IFNs from various species. Like the IFN ω proteins, the IFN τ proteins contain a C-terminal extension of 6 amino acids. In addition, the τ IFNs exhibit antiviral activity in common with other IFNs, and are able to bind the same receptor as IFN α , β and ω .

Regulation of IFN α expression

IFN α and IFN β gene expression is induced upon viral infections. The induction is transient and involves transcriptional activation by several transcription factors, which bind to upstream regulatory *cis*-elements. The region involved in the virus inducibility of the human IFN α genes is known as the virus-inducible element or VRE. Similarly, it was reported that the IE (inducible element), which overlaps with the VRE, was able to confer inducibility to murine IFN α genes. These elements contain repeats of the AGTGAA motif, or the variants of GAAANN and form cooperative binding sites for the positive factors IRF1 (IFN regulatory factor 1), TG-binding factor and α F1 (α factor 1). A fourth factor, IRF2, binds to the same element as IRF1 and can suppress the function of this factor. However, the precise role of these factors in the regulation of the IFN α genes remains to be established. Differences in the VRE sequences of individual IFN α genes in both men and mice have been suggested to account for differences

in the activity of their respective promoters. The IFN β gene is regulated in a different way, which is described in the entry on 'Interferon β '.

In general, no IFN activity is found in normal sera or organs, however some evidence is provided that small amounts of IFNs are constitutively produced by peritoneal macrophages *in vivo*.

IFN α / β signal transduction

All cellular responses to IFNs require the interaction of the ligand with a low number of high-affinity, species-specific cell surface receptors. There are two types of IFN receptors: type I and type II. The functional type I IFN receptor is composed of at least two transmembrane subunits and permits the productive binding of IFN β and the many related subtypes of IFN α . IFN α / β subspecies differ considerably in their affinity for the receptor, which correlates with the level and type of biological activity. The type II receptor also consists of two subunits and specifically binds IFN γ . The pathways activated by type I IFNs are slightly different from those activated by type II IFN, which will be discussed in the article on 'Interferon γ receptor'. Interestingly, the signal transduction pathway used by type I and type II IFNs has become a prototype for signaling from many cytokine receptors.

In response to type I IFN, within minutes the IFN α / β receptor activates two members of the JAK or Janus family of cytoplasmic tyrosine kinases, TYK2 and JAK1, that constitutively associate with the receptor cytoplasmic tail. Activated kinases become autophosphorylated and phosphorylate the receptor on specific tyrosine residues, creating docking sites for the transcription factors STAT1 and STAT2, that are members of a family known as STAT (signal transducers and activators of transcription). The STAT1 and STAT2 proteins subsequently become rapidly activated by tyrosine phosphorylation at a single site catalyzed by JAK1 and TYK2. This activation allows them to stably assemble into a STAT1–STAT2 heterodimer complex through specific src homology 2 (SH2) phosphotyrosyl interactions, and together with the DNA-binding subunit p48 (a member of the IRF family) join in the multiprotein complex ISGF3 (IFN-stimulated gene factor 3). ISGF3 translocates to the nucleus where it binds to the IFN-stimulated response element (ISRE; consensus sequence AGTTTCNNTTTCT/C, where N is any nucleotide) sequence in the promoters of IFN α / β -inducible genes (ISG), to initiate transcription. In addition to ISGF3, several other protein factors have been identified which recognize the ISRE: IRF1, IRF2, IRF3, ICSBP

(IFN consensus binding protein), Pip (Pu.1 interaction partner) (all members of the IRF family) and IBP1 (ISRE-binding protein 1). Although these factors all bind specifically to the ISRE, ISGF3 has been shown to be the primary factor involved in the early transcriptional activation of ISGs. ISGF3 is induced very rapidly by IFN α/β without novel protein synthesis. The kinetics of appearance and decline of ISGF3 and its lack of dependence on protein synthesis correlate with transcriptional activation and deactivation of ISGs. The precise role of the other ISRE-binding factors in the regulation of the ISGs, however, remains to be established.

Lately, a second class of early response ISG1 genes has been identified, that are activated by both type I and type II IFNs and contain an enhancer element known as gamma activated site (GAS; TTNNNNNAA). In response to both types of IFN, a transcription factor known as GAF (composed of a homodimer of phosphorylated STAT1) binds the GAS and activates transcription. GAF, like ISGF3, is resident in the cytoplasm of untreated cells, is activated in response to type I and type II IFNs, and then quickly migrates to the nucleus and binds DNA. Activation of GAF correlates with transcriptional activation of GAS-containing genes.

Recently, disruption of the gene for STAT1 in embryonic stem cells and in mice revealed that the STAT1 protein is required for all transcriptional responses to IFN. STAT1-deficient mice grow and

develop similar to wild-type animals, but show compromised innate immunity to viral disease (Figure 1).

IFN α/β -inducible genes

Type I and type II IFNs induce the expression of overlapping sets of genes. Some of these genes are induced in common by the type I and type II IFNs, whereas others seem to be preferentially induced by one of the IFN types. The similarities and differences in the biological properties of the type I and type II IFNs may be a reflection of partially overlapping and differential regulation of cellular genes by the two types of IFNs.

ISG mRNAs are detected in cells within about 1 hour of treatment with type I IFN. In some cases, the mRNAs accumulate to a steady-state level which is maintained for over 24 hours. In other cases, the mRNAs are induced to a peak level which then declines, despite the continued presence of IFN. The induction of gene expression by IFNs is often of great magnitude, reaching high rates of transcription from nearly undetectable levels. Although the induction is primarily at the transcriptional level, additional regulation at the post-transcriptional level has been proposed in certain cases. Induction of transcription will occur even in the absence of cellular protein synthesis. The transcriptional response of ISGs correlates with receptor occupancy. Some ISGs were also found to be directly inducible by virus or double-

Figure 1 STAT1-deficient mice are extremely susceptible to viral infections. Transcriptional responses to interferons (IFNs) are mediated by tyrosine phosphorylation and nuclear translocation of transcription factors of the signal transducer and activator of transcription (STAT) family. Disruption of the gene for STAT1 in embryonic stem cells and in mice revealed that the STAT1 protein is required for all transcriptional responses to IFN (both type I and type II). STAT1-deficient mice grow and develop similar to wild-type animals, but show compromised innate immunity to viral disease. These animals fail to survive in the presence of otherwise innocuous pathogens, including mouse hepatitis virus. Histological examination of liver tissue from STAT1-deficient animals dying of disease showed multifocal hepatic necrosis with syncytial cell formation (A) and scant inflammatory response, consistent with viral hepatitis (caused by infection with mouse hepatitis virus). Analysis of hepatic tissue taken from wild-type siblings demonstrated no pathology (B). (Courtesy of Dr JE Durbin and Dr DE Levy.) (See also color **Plate 8**.)

stranded RNA, in the absence of IFNs. The mechanism of this induction, which does not seem to involve ISGF3 or GAS, is still unclear.

A search for IFN-induced proteins responsible for mediating the antiviral and other effects of IFNs led to the identification of novel enzymes (e.g. two double-stranded RNA-activated enzymes: a protein kinase (PKR) and a 2',5'-oligoadenylate synthetase (2,5OAS)), cell surface molecules (MHC class I and class II antigens, Fc receptors) and a number of new proteins, like the murine Mx protein.

A direct role in the antiviral actions has been demonstrated for the Mx protein and PKR and the 2,5OAS systems. In Mx⁺ mouse strains, for example, the Mx1 gene is induced by IFN and confers resistance selectively to influenzavirus. The IFN-induced PKR protein phosphorylates translation initiation factor eIF-2 α which results in inactivation of this factor and consequently to inhibition of protein synthesis. PKR activation is dependent on double-stranded RNA, which is present in a cell only when a virus replicates its genetic material. Thus, protein synthesis is blocked by PKR in infected cells but not in healthy ones. The 2,5OAS family of enzymes which are induced by both type I and type II IFNs, also interfere with the production of viral proteins, but they do so by activating an enzyme called ribonuclease RNAase L, which cleaves RNA without any specificity before it can be translated into protein.

Some of the proteins that inhibit protein synthesis may also have a function in the growth-inhibiting effects that IFNs display on certain tumors in culture and in the body. For example, the IFN-inducible 9-27 gene encodes for an RNA-binding protein that inhibits Rev-mediated HIV-1 expression and vesicular stomatitis virus. On the other hand, this protein has also been implicated in the IFN-induced inhibition of cell proliferation. Recently, the IFN-inducible cyclin-dependent kinase inhibitor p21 has also been implicated in the growth-inhibiting effect of IFNs, by negatively regulating the cell cycle.

Despite the fact that over 30 IFN-inducible proteins have now been identified, unfortunately it remains largely unclear how exactly they mediate the biological effects of IFN.

Therapeutic use of IFN α

With all their impressive properties, IFNs have come under close attention as potential therapeutic agents. In particular, the antitumor effects of IFNs led to high expectations in the battle against cancer. Unfortunately, IFN did not turn out to be a magic bullet. An additional limitation that IFNs display in clinical use, especially IFN α , is that they can produce side-

effects, including fever, headache, chills, fatigue, anorexia, leukopenia and thrombocytopenia. Despite their current limitations, IFNs are now well established as useful drugs. IFN α is the most widely used and has received approval in many countries, including Food and Drug Administration (FDA) approval in the US, for several clinical indications. Since 1986 it has been used as a therapy against hairy-cell leukemia. Significant regression of the cancer is observed in more than 90% of patients. Since 1988, IFN α has been successfully used as a therapy against diseases associated with human papillomavirus infection such as juvenile laryngeal papillomatosis and condyloma acuminatum. Since that same year it has also been used in the treatment of Kaposi's sarcoma in patients infected with HIV. Around 30% of the patients who receive IFN α , however, withdraw from treatment because of side-effects associated with the high IFN α doses. In 1991, IFN α was licensed for the treatment of chronic hepatitis C (non-A, non-B hepatitis) and in 1992 for chronic hepatitis B. IFNs also have demonstrated efficacy in basal cell carcinoma, cutaneous squamous cell carcinoma, chronic myelogenous leukemia, early HIV infection, carcinoid, multiple myeloma and some low-grade lymphomas.

The IFN τ proteins, like the other IFNs, show potent antiviral properties as well as antitumor effects and are currently also considered as therapeutic agents. The most promising quality of the τ IFNs, from a clinical point of view, may be their low toxicity as compared to IFN α . This low toxicity suggests that human IFN τ might prove to be a safer alternative to the other IFNs in the near future.

IFN α dosages per treatment range from 1 million units in hairy cell leukemia to 18–36 million units in Kaposi's sarcoma. Therapy duration ranges from a few weeks in condyloma acuminatum patients to several months in chronic hepatitis C cases. The severity of side-effects of IFNs are dose related and observed in most patients receiving more than 1 million units of IFN per treatment.

Whereas IFNs have so far clearly shown their value in medicine as a monotherapy, they may turn out to be most helpful when combined with standard treatments such as surgery, chemotherapy or radiotherapy or in combination with other drugs. For example, IFN α in combination with tamoxifen is more effective against breast cancer than either drug alone. Likewise, in combatting HIV, IFN α in combination with zidovudine (AZT) enhances the drug's effects. Alternatively, strategies for gene therapy involving IFN genes are being developed to treat infectious diseases such as the acquired immune deficiency syndrome (AIDS). Although this kind of

therapy is still in a very early stage, it may be a promising tool in the near future.

INTERFERON β

Rainer Zawatzky, German Cancer Research Centre, Institute for Virus Research/ATV, Heidelberg, Germany

Helmut Jacobsen, F. Hoffmann-La Roche AG, PRP/Gene Technology, Basel, Switzerland

Interferon β (IFN β) and the multiple species of interferon α constitute the type 1 IFNs. The historical term 'fibroblast interferon' is misleading, since clearly more tissues than fibroblasts produce this type of IFN. Interferon β and α are related in a number of ways:

1. Their primary structure suggests that they originate from a common ancestor gene.
2. They may be produced by the same type of cell following the same inducing agent.
3. They bind to the same cell surface receptor and show an almost 100% overlap in their biological activities.

Thus, most of the antiviral and antiproliferative activities discussed below apply to IFN α also. Nevertheless, there are some observations that clearly point to a different functional role for IFN β *in vitro*. These observations include:

- the molecular mechanisms of IFN β induction;
- the concept of autocrine IFN β production during differentiation or physiological growth control; and
- different pharmacokinetics for IFN β and IFN α .

This entry on IFN β structure, induction and production will focus on human IFN β and include some

data on its murine counterpart. It is, however, anticipated that similar conclusions apply to other organisms, since in all mammalian species studied so far an equivalent structure of the IFN system has been found.

Structures of the IFN β gene and protein

The mature human IFN β is a glycoprotein of ~23 kDa apparent molecular weight. The entire primary sequence as deduced from complementary DNA consists of 166 amino acids which are preceded by a signal peptide of 21 amino acids. An N-glycosylation site has been identified at position 80 of the mature protein (Asn80-Glu81-Thr82). A disulfide bond between cysteines 31 and 141 is essential for biological activity. The more hydrophobic character of the IFN β protein is in agreement with a high content of leucine, tyrosine and isoleucine. The physiological significance of the carbohydrate moiety is still unclear, since unglycosylated recombinant IFN β retains its biological activity, although it has been suggested that glycosylation may contribute to its stability.

The IFN β gene has been mapped to human chromosome 9 in the vicinity of the IFN α gene cluster. Like the IFN α genes, the IFN β gene lacks any intron. Only one IFN β gene has been identified in human and mouse, whereas at least three closely related IFN β genes have been found in cattle.

Native murine IFN β has an apparent molecular weight of 35–40 kDa. The primary sequence of the mature protein consists of 161 amino acids preceded by 21 amino acids of signal sequence. There are three potential sites for N-glycosylation (at positions 29, 69 and 76) and one single cysteine residue at position 17. Thus, unlike human IFN β , the murine species does not require intramolecular disulfide linkage for biological activity. Like the murine IFN α genes, the murine IFN β gene is devoid of introns and has been localized to chromosome 4.

Induction and production of IFN β

Most cell types seem to be capable of producing IFNs under the appropriate conditions of induction. The type and amount of IFN produced, however, is extremely variable and depends on the given combination of cell type and inducer. Efficient inducers of IFNs include not only double-stranded RNAs (dsRNA) and viruses, but also bacteria or bacteria-derived lipopolysaccharide and protozoa.

There is no clear distinction between IFN α and IFN β inducers. Whether either or both types are produced depends to a large extent on the cell type and on the species. While dsRNA treatment of human fibroblasts will produce exclusively IFN β , treatment of murine fibroblasts will produce IFN β and IFN α . Following exposure to dsRNA, human blood monocytes will make IFN α , whereas murine macrophages make a mixture of IFN α/β . Thus, there seem to be cellular factors which convert the same inducing signal to a tissue specific pattern of expression. The following discussion will focus on the induction of IFN β by dsRNA and virus.

Regulation of IFN β gene expression

In general, the IFN β gene is only transiently activated following induction by virus or dsRNA. Maximum levels of IFN β mRNA are reached at around 6–8 h after induction and then gradually decrease to undetectable amounts by 18–24 h. In virus-infected cells, transcriptional activation is not dependent on *de novo* protein synthesis, in contrast to postinduction repression that is sensitive to protein synthesis inhibitor drugs. Expression of the IFN β is controlled by a transcriptional enhancer located between nucleotides –104 and –37 upstream of the transcriptional start site. Dissection of this DNA region has revealed the presence of four positive regulatory domains called PRDI to IV and one negative regulatory domain, NRDI, that partially overlaps with PRDII. When analyzed individually, the PRDs are unable to stimulate transcription unless they are present in multiple copies. However, such

multimerized subunits of the IFN β gene promoter show only moderate inducibility and, in addition to virus, are also responsive to tumor necrosis factor α (TNF α), IFN γ or cAMP. In contrast, the intact promoter is only inducible by virus and its activity exceeds by far that of any synthetic construct.

The PRDI region comprises a sequence between nucleotides –77 and –64 and was the first functional element identified within the IFN β enhancer. There is a strong sequence similarity between PRDI and an adjacent element named PRDIII, giving rise to the assumption that these sequences arose by duplication of a common ancestor. Two nuclear proteins, interferon regulatory factor 1 and 2 (IRF1, IRF2), have been shown to compete for a hexanucleotide sequence within PRDI. Both factors share extensive sequence homologies in their N-terminal parts which are involved in DNA binding; however, whereas IRF1 is a transcriptional enhancer, IRF2 represses IFN β expression. Following infection by virus, both mRNAs are induced and it is assumed that the finely tuned balance between these two factors is important for the shut-off of IFN β expression.

Nevertheless, the importance of IRF1 for the activation of PRDI is still a matter of debate. On the one hand, mutations within the PRDI element that reduce the affinity for IRF1 decrease the levels of virus-induced IFN β gene synthesis. In addition, IRF1 is not inducible in undifferentiated cells, which also lack the capacity to produce IFN β in response to virus. Upon retinoic acid-induced differentiation, however, these cells gain the capacity to express both IRF1 and IFN β . On the other hand, elimination of IRF1 by targeted gene disruption has been shown to result in deficient IFN β production only in response to dsRNA but not in response to virus. It has therefore been suggested that an alternative, IRF1-independent, pathway of IFN β induction also exists.

The PRDII element of the IFN β enhancer extends from nucleotides –64 to –55 and specifically binds transcription factors of the NF κ B/rel family. Among the four PRD elements, PRDII displays the strongest activity and it has been shown that oligomers of PRDII confer inducibility by virus but can also act as constitutive transcriptional activators. In the non-induced state the intact IFN β promoter is silent due to the presence of NRDI that partially overlaps with PRDII and further extends downstream to nucleotide –37. NRDI also contains a conserved 11 bp element at the 5' end with a strong silencing effect on constitutive NF κ B/rel-containing promoter constructs. NF κ B is necessary for induction of the IFN β gene by virus; it is, however, not sufficient since a variety of other activators of NF κ B fail to stimulate the gene promoter. In addition to NF κ B, the high mobility

group (HMG) protein I(Y) has been shown to bind to PRDII and to enhance DNA binding activity of the p50 and p65 subunits of NF κ B.

Like PRDII, the PRDIV element alone can also function as a virus-inducible enhancer when present in multiple copies. In the intact IFN β enhancer PRDIV is located between nucleotides -104 and -86. The activating transcription factor 2 (ATF2) specifically binds to a nonamer region within PRDIV, either as a homodimer or as a heterodimer with the cellular proto-oncogene *c-jun*. Similarly to NF κ B and PRDII, HMG I(Y) has also been found to specifically recognize DNA sequences adjacent to the ATF2/*c-jun* binding site at PRDIV. In addition, HMG I(Y) interacts with the basic/leucine zipper domains of ATF2/*c-jun* and facilitates the binding of the heterodimer to PRDIV.

Recently, it has been proposed that HMG I(Y) facilitates the assembly of an 'enhanceosome' which constitutes the regulatory unit for the control of IFN β gene expression. According to this model the enhanceosome of the IFN β promoter comprises a DNA complex including two or more HMG I(Y) molecules and at least three transcription factors that bind to PRDI-IV.

IFN β mediated biological activity

At least five complex types of biological activity are mediated by IFNs: 1) receptor binding, 2) antiviral, 3) cell growth inhibitory, 4) immunomodulatory, and 5) antitumor activity. This summary will focus on the first three activities.

The IFN α / β receptor

Any IFN-mediated activity requires binding to a specific receptor on the cell surface. The number of receptors varies from some hundred to a few thousand per cell. All human IFN α species and IFN β share the same type I IFN receptor to which they bind with similar affinity (K_d ranging from 1 to 2×10^{-10} M). Receptor-bound IFN is internalized via receptor-mediated endocytosis. The receptor is composed of two chains with molecular weights of 115 kDa and 102 kDa. The gene for the type I IFN receptor α chain encodes the 557 amino acids of the 115 kDa protein. A second, recently identified cDNA encodes for a 51 kDa protein of 331 amino acids, but it is not yet clear whether the 102 kDa chain consists of two disulfide-linked 51 kDa subunits. When expressed in mouse cells, only the 51 kDa chain displays high-affinity binding for all type I IFN species including IFN β , but is biologically inactive. The 115 kDa chain only binds one IFN α subspecies and not IFN β ; however, a tenfold increase in ligand

affinity is observed when the 51 kDa and 115 kDa chains are coexpressed in mouse cells, indicating that both receptor chains associate upon binding of IFN to form a high-affinity ternary complex. In addition, they also seem to be involved in signal transduction in human cells via two cytoplasmic tyrosine kinases. Jak1 and tyk2, that are constitutively associated with the native 102 kDa and 115 kDa chains, respectively.

On the basis of nucleotide sequence homology, a murine homolog of the human 115 kDa receptor chain has been identified and expressed in human cells. Similar to the corresponding human counterpart, this chain also displays selective binding characteristics for some but not all type I mouse IFN species, suggesting that the natural mouse IFN receptor also consists of two chains. Studies using mutant mice lacking this receptor chain proved the important role of the IFN system *in vivo* since these animals showed high susceptibility to infection by several viruses including vesicular stomatitis, Semliki Forest, lymphocytic choriomeningitis and vaccinia virus. These findings demonstrate that mouse cells probably also have an additional receptor chain and that the loss of one functional subunit results in failure to respond to IFN.

Antiviral activity

Exposure of cells to IFNs renders them less permissive to viral replication. Current evidence suggests that this antiviral state is composed of a number of independent antiviral mechanisms which may interfere at various stages of the viral growth cycle. Thus, it has been demonstrated that IFN treatment inhibits 1) virus uptake (vesicular stomatitis virus (VSV)), 2) events during late virus uncoating or primary transcription (e.g. SV-40, herpes simplex virus type 1 (HSV-1), influenza virus, VSV), 3) viral protein synthesis (e.g. reovirus, picornavirus, VSV, SV-40), and 4) virus maturation and release (retrovirus, HSV-1). Further targets for antiviral activity may exist.

The mechanisms by which these inhibitions are brought about are not completely understood. Crucial to the translational inhibition are two pathways which require dsRNA for activation. One pathway leads to increased degradation of RNAs through stimulation of the IFN-induced 2',5'-oligoadenylate synthetase and activation of an endoribonuclease by its product, 2',5'-oligoadenylate. This RNAase is involved in IFN-mediated resistance to encephalomyocarditis virus but not to VSV, as shown by overexpression of a dominant negative mutant in cell culture. Central to the second pathway is an IFN-induced protein kinase (PKR), which upon activation by dsRNA phosphorylates the translation factor eIF-2 α and thus blocks protein synthesis at the level of

binding of mRNAs to ribosomes. In the intact cell, these translational control mechanisms are fairly specific for viral gene expression, leaving cellular protein synthesis unchanged.

The Mx proteins are a family of related, IFN-induced proteins which mediate resistance to specific virus groups. The murine Mx1 is a nuclear protein which blocks primary transcription of influenza A virus. Its human homolog is a cytoplasmic protein which in addition to influenza A virus inhibits the replication of VSV. Both proteins have a GTPase activity, however its importance for the antiviral activity is currently unknown.

Some proteins involved in IFN signaling such as STAT1 and IRF1 are also required for establishing an antiviral state. IRF1 has been shown to exhibit antiviral properties in the absence of IFN whereas STAT1, the common subunit of the signal transduction and activator of transcription protein family, requires phosphorylation on a tyrosine residue following IFN treatment since a mutation in this position prevents its activation, nuclear translocation and IFN-induced virus resistance.

In addition to these intracellular antiviral activities whose target is the replicating virus, IFN-mediated antiviral protection in the organism may involve effector cells of the immune system, e.g. natural killer (NK) cells, macrophages or cytotoxic T cells, whose target is the infected cell itself.

Cell growth inhibiting activity

The antiproliferative activity of IFN type 1 has been observed on cultured cells from various tissues, e.g. fibroblasts, epithelial cells, endothelial cells, and cells of the hematopoietic system. Furthermore, normal, transformed and tumorigenic cells have been shown to be sensitive to this activity, although the degree of sensitivity varies widely. It is now clear that multiple parallel pathways are involved in IFN-mediated growth inhibition and some of the molecular targets have been identified during the past few years. In IFN-sensitive cell lines, strongly reduced DNA-binding activity of the transcription factor E2F was observed and found to be associated with growth arrest in the G₀/G₁ phase of the cell cycle. E2F activates several genes involved in cell cycle regulation and recent reports have documented an IFN-mediated inhibition of cyclins and cyclin-dependent kinases (cdk), indicating that IFN acts, at least in part, by functional modulation of E2F. Most likely, inhibition of cdk also results in reduced phosphorylation of the retinoblastoma protein (pRB), a tumor suppressor gene known to form a complex with E2F, thus preventing its interaction with DNA target

sequences. Upon phosphorylation, pRB detaches from E2F and the released factor becomes active. In addition, IFN also induces expression of pRB which predominantly exists as the underphosphorylated form able to interact with E2F. Since E2F also drives the expression of *c-myc*, there is also a concomitant inhibition of this cellular proto-oncogene in IFN-treated cells. The transcription factor IRF1 has also been shown to cause inhibition of cell proliferation when overexpressed in cell culture. IRF1 is not only involved in the regulation of IFN gene expression but is itself inducible by IFN and transactivates IFN-stimulated genes through binding to the IFN-stimulated response element (ISRE). The dsRNA-dependent kinase PKR is induced by IRF1 and there is substantial evidence that PKR represents a downstream target of IRF1-mediated growth inhibition since cells engineered to overexpress a dominant negative mutant of PKR fail to respond to the antiproliferative action of IRF1.

'Endogenous' IFN β induction

Circumstantial evidence points to a low level of IFN β production under various conditions in cell culture and *in vivo* in the absence of known IFN inducers, a situation which has been described as physiological, spontaneous or autocrine IFN β production. This endogenous IFN β has been implicated in control of cell growth and differentiation. Primary mouse macrophages proliferate in response to macrophage colony-stimulating factor (M-CSF). Inclusion of an antimouse IFN α/β serum further stimulates the mitogenic response and increases the susceptibility of the culture to virus infection. In mouse myeloid M1 cells, IFN β mRNA has been detected following differentiation by cytokines (e.g. M-CSF, TNF α , interleukin 6 (IL-6)) and differentiation was inhibited by antiIFN β serum. Activities similar to those of IFN β have also been demonstrated in dimethyl sulfoxide (DMSO)-differentiated Friend erythroleukemia cells and in phorbol-12-myristate-13-acetate (PMA) differentiated U937 cells.

Endogenous IFN β production is not restricted to cells of hematopoietic origin; IFN β RNA has been found in IL-1- and TNF-treated Hep-2 cells and is of crucial importance to the antiviral activity of TNF, whereas in FS-4 fibroblasts the mitogenic stimulus provided by TNF is enhanced by antibodies against IFN β .

Why IFN β ?

The division of the IFNs into one (or a few) IFN β and a multispecies group of IFN α which has so far

been found in all mammalian species, suggests a unique role for these different IFNs. This assumption, however, finds little support when one compares their biological activities, since the overlap seems to be almost complete and synergism has not been found when IFN α and IFN β are combined in treatment. Thus, the biological 'justification' for IFN β may be the tissue specificity of its expression and its pharmacokinetic behavior. From clinical experience, it is known that IFN β is more 'sticky' than IFN α , i.e. whereas the latter is easily found in the serum following intramuscular injection, IFN β administered by the same route is usually not found in the circulation. It has been assumed that, due to a faster uptake in tissues and in the lymphatic system, IFN β exerts its biological activity in close proximity to its site of production and is thus especially suited as an autocrine/paracrine effector in control of growth and differentiation.

INTERFERON γ

Jan Vilček and **Junming Le**, Department of Microbiology, New York University Medical Center, New York, NY, USA

The cytokine now known as interferon γ (IFN γ) was first described in 1965 by Wheelock as an interferon-like antiviral substance produced by leukocyte cultures stimulated with phytohemagglutinin (PHA). Although in the virus inhibition assay the factor was indistinguishable from IFN, Wheelock noted that, unlike typical IFN, the PHA-induced leukocyte-derived factor was inactivated by exposure to pH 2. Subsequently, other investigators showed that various mitogenic agents can induce the production of a factor with IFN-like antiviral activity in cultures of lymphocytes, especially T cells. In 1973, Youngner and Salvin showed that IFN derived from lymphocyte cultures by mitogenic stimulation is antigenically distinct from 'classical' IFN and they pro-

posed to term the former 'type II IFN'. Other investigators used the term 'immune IFN' to describe this IFN-like protein. In 1980, these earlier names were replaced with the term IFN γ . At the same time, the names IFN α and IFN β were introduced for the two antigenically distinct varieties of 'classical' or 'type I' IFN. The human IFN γ protein was first isolated by Yip and colleagues in 1981.

Cloning of the human IFN γ gene by Goeddel and coworkers in 1981 revealed that IFN γ is structurally distinct from the IFN α/β family. (There is a large family of mutually interrelated IFN α/β proteins, each encoded by a separate structural gene.) Likewise, the cellular receptor for IFN γ is distinct from the receptor for IFN α/β .

The IFN γ gene and protein

Only a single IFN γ gene has been identified in all animal species examined. The human IFN γ gene has been mapped to chromosome 12, the structural gene for murine IFN γ is on chromosome 10 (Table 1). The overall organization of the IFN γ gene is very similar in different animal species, comprising three introns and four exons.

The human IFN γ gene encodes a mature protein 143 amino acids long, in addition to a 23 amino acid signal peptide sequence removed before the secretion of the molecule. The protein is rich in basic amino acids. Native IFN γ was found to lack between 9 and 16 residues from the C-terminus, apparently due to exopeptidase digestion during or after secretion. There are two potential N-glycosylation sites at positions 28 and 100. Under denaturing conditions, the fully glycosylated molecule has an apparent molecular weight of 25 kDa, but in some naturally produced molecules only one of the two sites is glycosylated (resulting in the generation of a molecule with an apparent molecular weight of 20 kDa under denaturing conditions) and a small portion of the secreted IFN γ molecules apparently lacks carbohydrate altogether (having an apparent molecular weight of 15 kDa). There is no evidence that the presence or absence of carbohydrate has a significant influence on the functional activity of IFN γ . Nonglycosylated *Escherichia coli*-derived recombinant human IFN γ shows the same spectrum of biological activities as natural, glycosylated human IFN γ . Native human IFN γ is a homodimer, with an apparent molecular weight of approximately 40–50 kDa on gel filtration columns. X-Ray crystallographic analysis of recom-

binant IFN γ indicates that the sites contacting the cell surface receptor contain segments from both the N- and C-termini of the IFN γ dimer.

The murine IFN γ gene encodes a 134 amino acid-long mature peptide (i.e. nine residues shorter than human IFN γ), with a cysteine at the C-terminus. However, the actual C-terminal sequence of native murine IFN γ is not known. Human and murine IFN γ are only about 40% homologous at the amino acid level. Therefore, human IFN γ is virtually inactive in mouse cells, and so is murine IFN γ in human cells.

Generation of IFN γ

Although production of trace amounts of IFN γ by monocytic and some other cells has been reported, lymphoid cells are the only significant source of this cytokine. Natural killer (NK) cells, helper T (T_H) cells, cytotoxic T (T_C) cells and some B cell lines all generate IFN γ upon appropriate stimulation. IFN γ production in these cells can be induced by various activating treatments; in T cells IFN γ can be induced by polyclonal activators, e.g. PHA, concanavalin A or antibodies to CD3, or by antigen-specific, clonally restricted activation. In helper T cells, IFN γ production is abundant by T_H1 cells and is characteristically absent in T_H2 cells. The cytokine interleukin 12 (IL-12) is now recognized to play an important role in the regulation of IFN γ production by both NK and T cells. In the intact organism, during early stages of an infection, lipopolysaccharide (LPS) and other products of bacteria, as well as components of protozoan parasites and other infectious agents, induce IL-12 production in monocytes and macro-

Table 1 Major characteristics of IFN γ

Location of structural gene	Chromosome 12 (human) Chromosome 10 (mouse)
Location of receptor genes	Chromosome 6 and 21 (human) Chromosome 10 and 16 (mouse)
Main cellular sources	T cells (mainly T_H1 and T_C), NK cells
Major biological actions	Activation of monocytes/macrophages Induction of class I and II MHC molecules Promotion of antigen processing and presentation by accessory cells Stimulation of high-output nitric oxide production Modulation of immunoglobulin synthesis Promotion of T_H1 response, inhibition of T_H2 response Modulation of cytokine synthesis Inhibition or stimulation of cell growth Inhibition of the multiplication of viruses and some other intracellular infectious agents Inhibition of tumor growth
Roles in host resistance and disease	Protection against infectious agents (mainly through innate immune mechanisms) Increased production during infections can contribute to pathology (together with TNF α , lymphotoxin (TNF β) and some other cytokines) Increased production at a local site may promote autoimmune disease

phages. IL-12, together with IL-1, tumor necrosis factor α (TNF α) and some other cytokines produced by activated macrophages, then stimulates IFN γ generation in NK cells and subsequently in T cells. IFN γ , in turn, promotes its own production through complex regulatory circuits. In contrast, cytokines associated with the T_H2-type response, notably IL-10 and IL-4, inhibit IFN γ generation. Glucocorticoids and transforming growth factor β (TGF β) also downregulate IFN γ production.

The induction of IFN γ appears to be regulated mainly at the transcriptional level. A combination of several positive and negative regulatory elements located in the 5'-flanking region and in the introns of the IFN γ gene is thought to govern the expression of IFN γ , but the details of this process have not yet been fully elucidated. In addition, IFN γ synthesis can be regulated by the level of DNA methylation and post-transcriptionally by changes in mRNA stability or translation efficiency.

The IFN γ receptor and molecular mechanisms of action

The biological actions of IFN γ can be attributed to its ability to activate or inhibit the expression of specific target genes. All biological actions of IFN γ require the binding of IFN γ to specific cell surface receptors, expressed on virtually all types of cells. The receptor is composed of two chains, the ligand-binding α chain and the accessory β chain, which are encoded by genes located on two different chromosomes (Table 1). Although binding of IFN γ to the receptor is the function of the α chain, IFN γ binds with higher affinity in the presence of the β chain. IFN γ signaling is initiated by the formation of a multisubunit complex that contains both IFN γ receptor chains and IFN γ .

IFN γ signaling leading to activation of gene expression proceeds via the JAK-STAT pathway, so named because it involves the activation of receptor-bound JAK (Janus) tyrosine kinases, followed by the tyrosine phosphorylation and resulting activation of the signal transducer and activator of transcription 1 (STAT1) protein. IFN γ binding first brings about dimerization of the receptor α chain, thereby creating a binding site for the receptor β chain and leading to the activation of the JAK1 and JAK2 kinases. The activated JAK1 kinase phosphorylates a specific tyrosine residue on the cytoplasmic domain of the IFN γ receptor α chain, thus creating a docking site for the SH2 domain-containing STAT1 protein. Docking of STAT1 is followed by its tyrosine phosphorylation and subsequent release from the receptor. Activated STAT1 protein forms homodimers that translocate

to the nucleus and bind to DNA recognition sequences (termed interferon γ -activated sites, GAS) present in some IFN γ -inducible genes, thereby stimulating their transcription. In addition, activated STAT1 protein can form a heterocomplex with a protein termed p48, and this heterocomplex binds to other DNA recognition sequences (termed interferon-stimulated response elements, ISRE) present in some IFN γ -inducible genes, and thus activate their transcription. Some genes thus activated by IFN γ encode transcription factors, which then can activate additional genes. One transcription factor whose synthesis is induced by IFN γ is IRF1 (interferon regulatory factor 1). This is required for the IFN γ -induced activation of several genes, including the murine gene encoding the inducible nitric oxide synthase (iNOS), an enzyme responsible for the high-output nitric oxide production that mediates the killing of intracellular infectious agents and tumor cells. Another transcription factor induced by IFN γ is CIITA (class II transcriptional activator) responsible for the activation of class II major histocompatibility complex (MHC) genes.

Recent progress in the understanding of the pathways of intracellular signaling revealed why there are many similarities in the actions of IFN α/β and IFN γ , despite the fact that they are structurally dissimilar and bind to different receptors. It is now known that the IFN α/β receptor activates a similar pattern of JAK-STAT signaling as the IFN γ receptor, with some signaling proteins being shared (e.g. the JAK1 kinase and STAT1 protein) and some being utilized only in IFN α/β signaling (Tyk2 kinase and STAT2 protein) or only in IFN γ signaling (JAK2 kinase). Among the genes known to be activated by both IFN γ and IFN α/β are some genes encoding proteins responsible for the antiviral action (2'-5'-oligoadenylate synthetase and a double-stranded RNA-dependent kinase termed PKR) and genes encoding class I MHC molecules. In contrast, class II MHC genes are inducible by IFN γ but generally not by IFN α/β .

IFN γ action can also result in the inhibition of expression of some genes, such as genes encoding some other cytokines (chemokines). The inhibitory effects on gene expression can occur either at the level of transcription or post-transcriptionally, but the mechanisms of these inhibitory actions have not been fully explained.

Immunoregulatory actions of IFN γ

IFN γ plays a major role in the activation of monocytes or macrophages, resulting in their enhanced tumoricidal and microbicidal activities. Bacterial lipopolysaccharide (LPS) or TNF α and IL-1 can act

synergistically with IFN γ in this process. IFN γ stimulates monocytes/macrophages to synthesize TNF α , which mediates resistance to intracellular bacteria and the killing of some types of tumor cells. Monocyte/macrophage activation by IFN γ is accompanied by the release of the toxic gaseous compound nitric oxide (NO) which, in conjunction with reactive oxygen intermediates, mediates the killing of intracellular infectious agents and tumor cells. IFN γ is also known to enhance the expression of high-affinity Fc receptors for immunoglobulin G (IgG) on monocytes/macrophages, and this action may play a role in the stimulation of antibody-dependent cellular cytotoxicity (ADCC). Many examples of a differentiation-inducing activity of IFN γ in myelomonocytic cell lines have been described. In addition to their actions on monocytes/macrophages, IFNs (both IFN α/β and IFN γ) can activate other cytotoxic effector cells, most notably NK cells and cytotoxic T cells. In neutrophils IFN γ induces high-affinity IgG Fc receptors, leading to increased phagocytosis and cytotoxicity.

IFN γ can enhance antigen presentation and immune recognition in T cell-mediated immunity. IFN γ stimulates the expression of both class I and class II MHC molecules on various cell types by activating transcription of the respective structural genes. IFN γ enhances the expression of class II MHC molecules on accessory cells that constitutively express these proteins (monocytes, macrophages and dendritic cells) and induces the *de novo* synthesis of class II MHC genes in other cells, such as skin fibroblasts, vascular endothelial cells, thyroid epithelial cells and astrocytes. As a result of class II MHC molecule induction, these cells acquire an ability to function as antigen-presenting cells, and can thus participate in the process of specific immune recognition. To date, IFN γ is known as the most potent inducer of class II MHC expression, although some other cytokines (e.g. IL-4, IL-10, TNF α and granulocyte-macrophage colony-stimulating factor (GM-CSF)) also enhance the expression of these proteins in different types of cells. IFN γ also induces the expression of other MHC-encoded genes involved in antigen presentation such as TAP-1, TAP-2, and proteasome subunits. By inducing the peptide transporters TAP-1 and TAP-2, IFN γ promotes the translocation of antigenic peptides from the cytosol into the endoplasmic reticulum where the peptides bind to MHC molecules. By inducing the proteasome subunits LMP2 and LMP7, IFN γ alters the proteolytic specificity of proteasomes, facilitating the generation of peptides for antigen presentation.

IFN γ also has a regulatory role in the control of immunoglobulin isotypes produced by activated B

cells. IFN γ enhances the secretion of IgG2a by LPS-stimulated purified B cells *in vitro*, and concomitantly inhibits the production of IgG1, IgG2b, IgG3 and IgE while sparing IgM synthesis. There is evidence that IFN γ exerts its unique IgG2a-inducing effect directly on B cells, by both increasing the frequency of precursors of IgG2a⁺ cells and enhancing the number of IgG2a⁺ daughter cells emerging from each precursor. Also, IFN γ was found to enhance serum IgG2a and reduce serum IgG1 levels in mice immunized with *Brucella abortus*. Similar effects of IFN γ on IgG levels were observed in mice injected with anti-IgD antibodies; in addition, treatment with IFN γ also suppressed serum IgE levels in these mice. In contrast to IFN γ , IL-4 can stimulate the secretion of IgG1 and IgE, and suppress IgG2a secretion. Therefore, the relative quantities of IFN γ and IL-4 produced during an immune response are thought to regulate the selective production of immunoglobulin isotypes.

As mentioned, IFN γ production is a hallmark of the T_H1 response. Not only is IFN γ produced by T_H1 cells and not by T_H2 cells, IFN γ can also selectively inhibit the growth of T_H2 cells while sparing T_H1 cells. IFN γ can exert immunomodulatory actions indirectly, by affecting the generation of other cytokines. In monocytes/macrophages, IFN γ enhances IL-12 and TNF α production. IFN γ also promotes the T_H1 response by augmenting IL-12-induced T_H1 cell development.

IFN γ alone, or in combination with TNF α , induces chemokine secretion by endothelial cells and monocytes. (However, in other situations IFN γ can selectively inhibit chemokine production.) Furthermore, IFN γ can modulate cytokine receptors, e.g. the expression of TNF receptors in a variety of cells is enhanced by IFN γ action. It is also apparent that the actions of IFN γ are modified by the presence of other cytokines; many examples of synergistic and antagonistic interactions involving IFN γ and other cytokines (e.g. TNF α , lymphotoxin (TNF β), IL-1, IFN α/β) are known.

Another important action is the ability of IFN γ to augment the expression of the adhesion receptor ICAM-1 on vascular endothelial cells, leading to an increased adhesion of LFA-1-expressing cells. In this activity too, IFN γ acts cooperatively with TNF α or IL-1. This action is thought to contribute to the recruitment of lymphocytes to a local inflammatory site.

IFN γ was shown to be involved in the regulation of apoptosis in lymphocytes. Thus, pre-B cells can undergo apoptosis when exposed to IFN γ ; T cell receptor cross-linking-induced T_H1 cell apoptosis also requires IFN γ . The level of IFN γ receptor

expression on lymphocytes appears to be critical in the outcome of IFN γ actions; high-level expression tends to be associated with apoptosis, whereas low-level expression often leads to IFN γ -induced proliferation.

Roles in disease and therapeutic applications

A better understanding of the roles of IFN γ in the intact organism is emerging from studies with animals in which either the gene encoding IFN γ or the gene encoding the α chain of the IFN γ receptor has been inactivated by gene targeting. The major defect in animals that lack functional IFN γ (but retain the functions of IFN α/β) is a decreased ability to resist infection with some bacteria (*Listeria*, *Mycobacteria*), parasites (*Leishmania*) and viruses (vaccinia, Theiler's virus). Other changes seen in mice lacking functional IFN γ include an increased resistance to the toxic action of bacterial LPS and a decreased production of some other cytokines (TNF α , IL-1, IL-6 and IL-12). Such mice also showed a decreased capacity to develop protective immunity against *Plasmodium yoelli* sporozoites and against pseudorabies virus. There was also an altered pattern of generation of immunoglobulin isotypes, most notably a decrease in IgG2a production.

Several studies investigated the consequences of an aberrant expression of IFN γ in transgenic mice. Overexpression of murine IFN γ led to increased class I and II MHC expression, localized inflammation and tissue destruction. In a recent study aberrant expression of IFN γ in the neuromuscular junctions produced myasthenia gravis-like symptoms.

In view of its stimulatory action on MHC expression and antigen presentation IFN γ has long been suspected to play a role as a mediator of autoimmunity. However, it appears that the role of IFN γ in autoimmune disease may vary depending on the stage of the disease process or site of action. McDevitt and coworkers showed that in complete Freund's adjuvant (CFA)-induced arthritis in rats, administration of IFN γ 24 h before CFA caused an enhancement of arthritis, whereas injection of IFN γ 24–48 h after CFA suppressed the disease. In collagen-induced arthritis in mice, locally injected IFN γ promoted arthritis whereas systemically administered IFN γ was protective. There are other diseases in which IFN γ apparently plays a dual role. While there is evidence that IFN γ is an important factor in host defenses against some infections, recent data from animal models suggest that IFN γ may contribute to the pathology in septic shock, cerebral malaria and cachexia associated with tumor growth. These

adverse effects may be due at least partly to the ability of IFN γ to promote the generation of toxic levels of TNF α and to synergize with TNF α .

Many recent studies have investigated the effects of artificial overexpression of IFN γ (by introduction of cDNA expression vectors) on the ability of tumor cell lines to generate tumors in mice. In several models IFN γ -producing tumor cells were rejected due to the efficient generation of tumor-specific cytotoxic CD8⁺ T cells. However, in one study tumor cells transfected with IFN γ cDNA showed an increased metastatic potential.

In view of its many immunoregulatory actions, recombinant IFN γ has been tested in clinical trials in humans. Many of the trials were in patients with malignancies. Although some clinical responses have been seen (e.g. in renal cell cancer), the value of IFN γ in neoplastic diseases has not been confirmed in controlled clinical trials. One approved therapeutic application of IFN γ is in patients with chronic granulomatous disease, a rare genetic disorder in which defective phagocyte function represents the major clinical problem. Administration of IFN γ in these patients resulted in a significant improvement in the ability of their phagocytes to kill bacteria and reduced the incidence of life-threatening infections. The use of IFN γ for the treatment of some chronic infections affecting macrophages (e.g. leishmaniasis, toxoplasmosis, tuberculosis) is under consideration. Low doses of IFN γ were reported to have a beneficial effect in some patients with rheumatoid arthritis and in Germany IFN γ has been licensed for the treatment of this disease.

INTERFERON γ RECEPTOR

Jerome A Langer, Department of Molecular Genetics and Microbiology, University of Medicine and Dentistry of New Jersey-Robert Wood Johnson Medical School, Piscataway, New Jersey, USA

The interferon γ receptor (*ifngr*; IFN γ R) is a cell surface glycoprotein complex that uniquely binds interferon γ (IFN γ) initiating cellular responses (antiviral, macrophage activation, immunomodulatory). Recent progress includes the identification of critical molecular components, determination of the structures of the ligand and receptor, elucidation of a major intracellular signaling path-

way and investigation of the physiological roles of the IFN γ system (Table 1).

The *ifngr* consists of at least two glycoproteins (Table 1). *ifngr-1* (IFN γ R1 or α chain) is necessary and sufficient for high-affinity IFN γ binding (K_d of about 0.85 nM); however, biological activity and intracellular signaling require a second cell surface transmembrane protein, *ifngr-2* (IFN γ R2; accessory

factor 1 or β chain), which does not independently bind IFN γ , although the *ifngr-1/ifngr-2* complex binds IFN γ with about 2–5-fold higher affinity than does *ifngr-1* alone. The gene for *ifngr-1* is on human chromosome 6q, while that for *ifngr-2* is on human chromosome 21q, in a cluster with several known cytokine receptor genes, including both known components of the type I IFN (IFN α/β) receptor. *ifngr-1* and *ifngr-2* proteins have a tripartite structural motif: an N-terminal extracellular ligand-binding domain is connected to the C-terminal intracellular domain by a short hydrophobic membrane-spanning sequence which is probably α -helical. N- and O-linked glycosylation contribute to the apparent molecular size of the mature proteins. *ifngr-1* and *ifngr-2* are members of the cytokine receptor 2 structural family, as are the known subunits of the type I IFN receptor and the interleukin 10 (IL-10) receptor. Their extracellular portions are formed by two fibronectin III (FBN III)-like domains (Figure 1). The coexpression of human *ifngr-1* and *ifngr-2* in heterologous cells is sufficient for high-affinity ligand binding and for one or more biological activities, the latter depending on the experimental system employed. Additional receptor components or associated proteins may yet be discovered.

The three-dimensional structure of homodimeric IFN γ complexed with two molecules of the ligand-binding extracellular domain of *ifngr-1* (Figure 1) shows extensive contact between the ligand and receptor, including residues from several loops of each FBN III domain, in a manner reminiscent of the human growth hormone complex with its receptor. However, the membrane-proximal FBN III subdomains of the two bound *ifngr-1* receptors do not

make close contact with each other, leading to the suggestion that *ifngr-2*, not included in this crystalline complex, might interact in this region. It is unclear whether direct interactions with IFN γ help recruit *ifngr-2* into the active ligand–receptor complex.

Binding of IFN γ to the receptor activates the cell via a JAK/STAT (Janus Kinase/Signal Transduction and Activator of Transcription) pathway. While the order of events has not totally been established, IFN γ binding likely induces dimerization of *ifngr-1*, with the recruitment of *ifngr-2*, producing an activated complex of one IFN γ dimer, two *ifngr-1* chains and two *ifngr-2* chains. Jak1 and Jak2 tyrosine kinases are rapidly recruited, activated and phosphorylated. The subsequent phosphorylation of *ifngr-1* on its cytoplasmic domain creates a binding site for the cytoplasmic latent transcription factor STAT1 α through its SH2 (Src homology 2) domain. STAT1 α is consequently phosphorylated, leading to its dissociation from the receptor and homodimerization. The phosphorylated STAT1 α homodimer enters the nucleus through an undefined mechanism and serves as a transcription factor for genes having GAS (IFN Gamma Activated Sequences) elements in their 5' regulatory regions. The critical role of STAT1 α for IFN γ activity (and type I IFN activity) has been demonstrated in mice having a homozygous disruption of this gene. Molecular biological approaches have permitted the mapping of other important sites on the cytoplasmic segments of *ifngr-1* and *ifngr-2*. Whether other signaling or catalytic molecules are recruited to the active IFN γ –*ifngr* complex and whether the JAK/STAT pathway intersects with other known signaling pathways (e.g. mitogen-

Figure 1 Three-dimensional structure of the IFN γ homodimer complexed with two ligand-binding domains of the *ifngr-1* protein. Each extracellular ligand-binding domain, composed of tandem FBN III-type domains with seven β strands (represented as flat arrows), flanks the IFN γ homodimer (darker structure in the center, with α helices represented as coils). The receptor proteins would enter and traverse the plasma membrane (not shown) at the bottom of the figure. (Used by permission of Dr MR Walter.)

activated protein (MAP) kinase) is not known, nor have any phosphatases involved in the system yet been identified.

The distribution of the *ifngr* is undoubtedly related to its physiological roles. Most human and murine tissue culture cells bind IFN γ , with 100–10 000 receptors per cell. However, immunohistochemical studies of *ifngr* in human surgical specimens, while not as sensitive as radioligand-binding studies, suggest tissue-specific and developmental regulation of receptor expression. Thus, B cell areas of lymphoid tissues were strongly positive for *ifngr*, whereas lymphocytes in T cell areas did not have detectable expression. Moreover, evidence was presented for upregulation of *ifngr-1* during activation of T cells, and downregulation during B cell activation. Endothelial and epithelial tissues also varied considerably. *ifngr-2* appears absent in T_H1 (helper) cells, but not T_H2 cells, apparently underlying selective inhibition by IFN γ of T_H2 proliferation; *ifngr-2* may emerge as a marker for the T_H2 subset of helper T cells.

The physiological contribution of the IFN γ system is apparent in mice homozygous for targeted disruptions of the *ifngr-1* locus ('knockout' or *ifngr-1*^{0/0}). The IFN γ response is not critical for the *in vivo* control of several viruses (most examined were RNA viruses), but had an important role in some, such as vaccinia and Theiler's virus. On the other hand, a functioning IFN γ system was critical for defense against several intracellular bacteria (bacille Calmette–Guérin (BCG) and *Listeria*) and parasites (*Leishmania*). Developmental defects were not obvious in the immune system of *ifngr-1*^{0/0} mice, although effects possibly related to T_H1/T_H2 balance, such as immunoglobulin G (IgG) isotype ratios, were noted, as were effects on macrophage activation.

The inappropriate or prolonged activation of IFN γ has been related to various autoimmune and inflammatory reactions, and delayed-type hypersensitivity. The understanding and control of such responses would be aided by the development of IFN γ antagonists. No small-molecule peptidic or nonpeptidic antagonists have evolved, but experimentally useful macromolecular antagonists include the soluble ligand-binding domain of *ifngr-1* and antibodies to IFN γ or to *ifngr*. The soluble *ifngr-1* fragment has also been produced as a fusion protein with the immunoglobulin (Ig) heavy chain (an 'immunoadhesin'), enhancing its stability and serum half-life. These antagonists have demonstrated their efficacy in several mouse disease models. This receptor-based strategy for blocking IFN γ and other cytokines is seen in poxviruses: myxoma, which is immunosuppressive, encodes an *ifngr-1* homolog which is secreted from infected cells; however, a

definitive demonstration that this protein is a virulence factor is awaited.

Continuing basic and applied issues include the physiological regulation of the expression of *ifngr*, the interaction of its signaling pathways with others, and the development and application of receptor antagonists or mimics.

INTERLEUKIN 1 AND ITS RECEPTORS

Teresa Krakauer, Department of Immunology and Molecular Biology, US Army Medical Research Institute of Infectious Diseases, Frederick, Maryland, USA

Joost J Oppenheim, Laboratory of Molecular Immunoregulation, National Cancer Institute, Frederick, Maryland, USA

Interleukin 1 (IL-1) was originally described by Gery and Waksman in 1971 as a macrophage-derived, 'lymphocyte-activating factor' (LAF) with comitogenic effects on thymocytes and T cells. Subsequent studies revealed structural and biochemical similarities of LAF to other partially characterized mediators such as endogenous pyrogen, leukocytic endogenous mediator, B cell-activating factor, mononuclear cell factor, catabolin and osteoclast-activating factor. In 1979, the term IL-1 was proposed for the putative protein with all these pleiotropic activities.

The bioassay for LAF could be performed in multiwell assay plates and was sufficiently sensitive to effectively monitor purification and molecular cloning studies aimed at identifying IL-1. Before the advent of recombinant DNA technology, efforts to biochemically purify human IL-1 detected the existence of high (31 kDa) and low (17 kDa) molecular forms of LAF/IL-1, representing aggregated and mature forms, respectively. In 1984–1985, by using a combination of hydrophobic chromatography, gel filtration, isoelectrofocusing and high performance liquid chromatography, the low molecular weight protein was shown to consist of two molecules with different isoelectric points, pI 5.4 and pI 6.8. Cloning of cDNA for human IL-1 by Auron and colleagues in 1984 and March and coworkers in 1985 identified two distinct proteins with IL-1 activities, IL-1 α with a pI of 5.4 and IL-1 β with a pI of 6.8. All the aforementioned biological activities of IL-1 were manifested by recombinant IL-1. A third member of the IL-1 family, IL-1 receptor antagonist (IL-1ra), was cloned by Eisenberg and colleagues in 1990. IL-1ra was initially detected as an IL-1 inhibitor found naturally in the urine of patients with fever or myelomonocytic leukemia. IL-1ra acts as a specific antagonist of IL-1 α and IL-1 β by binding to IL-1 receptors without transducing a signal.

An endogenous mediator of host inflammatory responses, IL-1 also participates in regulating specific immune responses by enhancing the growth and differentiation of both B and T lymphocytes. It is active over low concentrations of 10^{-9} to 10^{-15} M. When locally produced by stimulated cells, IL-1 acts in an autocrine or paracrine manner to augment early non-specific inflammatory and later specific immune responses. When released in larger quantities into the circulation, IL-1 acts systemically to exert its endocrine effects such as activation of the fever center, the hypothalamus-pituitary-adrenal (HPA) axis and in inducing acute phase proteins.

IL-1 genes, mRNA and proteins

The three members of the IL-1 family are products of different genes located close to one another on human chromosome 2. The IL-1 α gene is 11 kb and the IL-1 β gene is 7.5 kb. Each gene contains seven exons, and transcription gives rise to a 2.1 kb mRNA for IL-1 α and a 1.6 kb mRNA for IL-1 β . The human IL-1ra gene spans 15 kb, has four exons, and the mRNA is 1.8 kb. At the nucleotide level, the homology between human IL-1 α and human IL-1 β is 45%. Sequence comparisons and analysis of mutational rates for IL-1 α , IL-1 β and IL-1ra by Eisenberg and colleagues suggests that all three molecules arose from a common ancestral gene through the process of gene duplication about 350 million years ago.

The regulatory sequences in IL-1 α and IL-1 β genes differ. The typical transcriptional promoter motifs, TATA box and CAAT box, are found immediately upstream from the transcription initiation site in IL-1 β , but are absent in IL-1 α . An NF-IL-6 site and a novel lipopolysaccharide (LPS)-inducible site have been identified in the IL-1 β promoter. Glucocorticoid regulatory elements are present in both genes. Both genes for IL-1 are rapidly transcribed upon

stimulation. IL-1 production is regulated at both the transcriptional and post-transcriptional level.

Unlike conventionally secreted proteins, IL-1 α and IL-1 β contain no hydrophobic signal peptide sequence and are not secreted via the classical secretory pathway. IL-1 is found in the cytoplasm but not in the endoplasmic reticulum or Golgi apparatus, and neither IL-1 α nor IL-1 β is *N*-glycosylated. Both IL-1 α and IL-1 β are synthesized as 31 kDa precursors (271 amino acids for IL-1 α and 269 amino acids for IL-1 β) which are proteolytically cleaved to generate the mature, 17 kDa proteins (159 amino acids for IL-1 α and 153 amino acids for IL-1 β). Most IL-1 α remains as pro-IL-1 α in the cytosol, while some is transported to the cell surface, where it becomes membrane-bound by a lectin interaction involving mannose residues on IL-1 α . Pro-IL-1 α as well as membrane-associated IL-1 α is biologically active, but IL-1 β is inactive and must be processed to the 17 kDa form before it can exert any biological effects. Several serine proteases are capable of cleaving pro-IL-1 β to the mature, biologically active form. However, an intracellular cysteine protease, named IL-1 β -converting enzyme (ICE) is required to cleave pro-IL-1 β specifically between Asp116 and Ala117 to generate the mature 17 kDa IL-1 β . ICE consists of both a 19.8 kDa and a 10.2 kDa subunit, which are derived from a 45.2 kDa proenzyme. ICE is found in most cells but requires two proteolytic cleavages for activation. The precise mechanism by which IL-1 is cleaved by ICE and is enabled to exit from the cell remains to be established. Both LPS and interferon γ (IFN γ) upregulate the expression of ICE. ICE does not cleave pro-IL-1 α , but knockout mice lacking the ICE gene fail to secrete IL-1 β as well as IL-1 α . IL-1 α is cleaved between Arg112 and Ser113 by calpain and other extracellular nonspecific proteases. Depending on cell type and the stimulant used, release or processing of IL-1 may not occur and pro-IL-1 may accumulate and be stored intracellularly. IL-1 release *in vitro* may also occur as a consequence of cell injury and cell death.

The precursor protein of IL-1ra is a single, non-glycosylated peptide of 177 amino acids with a 25 amino acid leader sequence. IL-1ra is secreted extracellularly in adherent immunoglobulin G (IgG)-stimulated monocytes as three structural variants; the two larger forms of approximately 22 kDa are glycosylation derivatives of the 18 kDa form (152 amino acids). All three forms of IL-1ra exhibit identical receptor binding, indicating that the *N*-linked sugar is not essential for this inhibitory activity (Figure 1).

IL-1 structure

Crystallography by Priestle and colleagues indicated that IL-1 β is a tetrahedron with the triangular faces formed by 12 β strands held together by hydrogen bonds. There are no intramolecular disulfide bonds. The hydrophobic core consists of side-chains arising from multiple positions along its primary sequence. The three-dimensional structure of IL-1 α is probably very similar to that of IL-1 β , as they have a similar frictional ratio and Stokes radius. Both N- and C-termini are exposed and residues involved in receptor binding and activation are located in a number of sites over the surface of IL-1. At the amino acid sequence level, IL-1ra is 26% homologous with IL-1 β and 19% homologous with IL-1 α ; the sequence of IL-1 β is 26% identical to that of IL-1 α . The hydrophilicity plot of IL-1ra is similar to that of IL-1 β , indicating similarities in tertiary structure.

Deletion mutation studies by Mosley and coworkers suggested that the minimum polypeptide size for retaining biological activities for IL-1 α is 140 amino acids, extending from 128 through 267. The minimum size for IL-1 β is 147 amino acids, representing amino acids 120 through 266. Both minimal IL-1 forms require an arginine at the N-terminus to retain biological activity. Most attempts to identify smaller fragments of IL-1 have failed but a fragment of nine residues of human IL-1 β (fragment 163–171) when fused to an antigen has been reported to have reproducible significant immunoadjuvant capacity. This fragment is absent from IL-1ra.

Cell source and inducers

Mononuclear phagocytes are the major cell source of IL-1. However every mature nucleated cell type examined has been shown to be capable of producing IL-1, including keratinocytes, dendritic cells, astrocytes, microglial cells, normal B lymphocytes, cultured T cell clones, natural killer cells, other leukocytes, fibroblasts, neutrophils, epithelial cells, endothelial cells and smooth muscle cells. Normal cells must be stimulated to produce IL-1. IL-1 production by macrophages can be triggered by a variety of proinflammatory stimuli, including bacterial cell wall products, LPS, microbial superantigens, zymosan, phorbol esters, muramyl dipeptide, antigens, mitogens, leukotrienes, activated complement components (C5a), immune complexes, ultraviolet irradiation, silica particles, viruses, parasites and other microorganisms. Agents that activate lymphocytes can stimulate macrophages to produce IL-1 either in response to direct cell interactions, or by

Figure 1 Interleukin 1: from genes to proteins.

producing cytokines such as lymphotoxin, granulocyte-macrophage colony-stimulating factor (GM-CSF), or IL-1 itself, which can stimulate macrophages and other cells to produce more IL-1.

The production of IL-1 β and IL-1ra in human monocytes is reciprocally regulated. *In vitro* studies by Arend and colleagues showed the production of both IL-1 β and IL-1ra by LPS-stimulated monocytes. Monocytes cultured adherent to IgG-coated surfaces exhibited no IL-1 β gene expression, but high levels of IL-1ra due to enhanced transcription and prolonged mRNA stability. The mechanism of this differential regulation of IL-1 and IL-1ra may involve cross-linking of different carbohydrate groups on the cell surface, resulting in differential signal transduction pathways. Other studies also suggest that production of IL-1 β and IL-1ra are differentially regulated by cytokines. For example, IL-4, IL-10 and transforming growth factor β (TGF β) decrease production of IL-1 β , but can concomitantly increase synthesis of IL-1ra in monocytes. Corticosteroids suppress the production of IL-1 α and IL-1 β but have no effect on IL-1ra. Studies of the kinetics of production of IL-1 generally reveal that IL-1 β is made

before IL-1 α , and IL-1ra is made last. In addition, patients treated with IL-1 β develop elevated plasma IL-1ra levels indicating that even IL-1 induces IL-1ra production.

Many cell types express all three IL-1 genes, but levels of IL-1 α , IL-1 β and IL-1ra vary widely. Keratinocytes express mostly IL-1 α and IL-1ra. Human monocytes produce predominantly IL-1 β while mouse macrophages produce mostly IL-1 α . During differentiation of monocytes into macrophages, production of IL-1ra is upregulated while production of IL-1 β is decreased. Thus IL-1ra is a major product of tissue macrophages, particularly during disease. Most of the IL-1 activity found in the circulation is IL-1 β whereas IL-1 α is more often detected on cell surfaces. Plasma concentrations of IL-1 β in normal subjects are usually undetectable (<40 pg ml $^{-1}$), except in women after ovulation and in subjects after strenuous exercise. Normal human subjects have circulating levels of IL-1ra in the range of 200–300 pg ml $^{-1}$. Studies by Dinarello and coworkers showed that during experimental endotoxemia in humans, peak levels of 150–200 pg ml $^{-1}$ of IL-1 β occurred at 3–4 h. In contrast, peak levels of 6000–8000 pg ml $^{-1}$

of IL-1ra typically occurred after 4 h and remained high for another 8 h.

Bioassay and other detection methods

Various laborious biological assays can be used to detect IL-1 α and IL-1 β activity. These include costimulation of murine thymocyte proliferation with phytohemagglutinin A, IL-2 production by IL-1-dependent T cell lines, stimulation of IL-1-dependent T cell line proliferation, stimulation of fibroblast proliferation, production of collagenase and prostaglandin E₂ (PGE₂) by synovial cells. The bioassay for IL-1ra is based on the inhibition of mitogenic activity of IL-1 in mouse thymocyte proliferation. Although bioassays are actually more sensitive than immunoassays, they are not generally preferred because they are more laborious, less reproducible and respond to other cytokines and therefore lack specificity. Moreover, other naturally occurring substances or inhibitors can interfere with the biological activity of IL-1 in bioassays. ELISA and RIA using monoclonal and polyclonal antibodies specific for each species of IL-1 are most commonly used. These assays have some limitations in that they cannot distinguish functional IL-1 from inactive material and can be affected by interfering molecules, such as soluble IL-1 receptors, which can prevent IL-1 binding to antibodies. Nevertheless, ELISAs are rapid, with sensitivity in the picogram per ml range, and are highly specific, as they can differentiate the three different forms of IL-1, which are often present together in biological fluids.

IL-1 receptors

Two distinct IL-1 receptors have been identified as shown by the cloning studies of Sims and coworkers. Both receptors are members of the immunoglobulin superfamily. The type I receptor is an 80 kDa transmembrane protein, 552 amino acids long, with a single 22 amino acid transmembrane region and a long cytoplasmic tail of 213 amino acids. Its extracellular ligand-binding region consists of three immunoglobulin-like domains. The type II receptor is a 60 kDa protein and is similar to the type I receptor in its extracellular and transmembrane regions. The type II receptor has a short cytoplasmic tail of 29 amino acids and is incapable of signal transduction. The type II receptor actually competitively inhibits IL-1 activity by acting as a 'decoy' receptor for IL-1, and regulates the level of extracellular IL-1.

IL-1 acts on target cells by binding with high affinity (K_d of 10^{-10} M) to IL-1 type I receptors. Type I receptors are found on T cells, endothelial cells,

hepatocytes, fibroblasts and keratinocytes, whereas type II receptors appear to have a more restricted distribution. Type II IL-1 receptors are the predominant receptor on B cells, monocytes and neutrophils. IL-1 α , IL-1 β and IL-1ra show detectable affinity for both types of IL-1 receptors. However, IL-1 α binds preferentially with somewhat higher affinity to type I receptor and IL-1 β binds preferentially to type II receptor. IL-1ra binds type I receptor with considerably higher affinity than it binds to type II 'decoy' receptor, and it can block the binding to type I receptor and consequent biological activities of both IL-1 α and IL-1 β . However, a 10- to 500-fold excess of IL-1ra may be necessary to achieve a 50% inhibition of the biological effects of IL-1 *in vitro*. Pro-IL-1 β does not bind to type I receptor and therefore has no detectable biological activity. The receptor binding affinity and biological activities of the pro and mature forms of IL-1 α appear indistinguishable. Despite the low number of type I receptors (200 per cell), all biological responses of IL-1 are mediated by type I receptors. A receptor occupancy of less than 5% per cell is sufficient to activate cells. These data suggest that a major amplification of IL-1 signal must occur after IL-1 ligand/receptor interaction. Recently, Greenfeder and colleagues identified an IL-1 receptor accessory protein which is the putative signal transducing subunit of the IL-1 receptor complex. IL-1 receptor accessory protein does not bind IL-1 directly but forms a complex with type I IL-1 receptor after it is bound by either IL-1 α or IL-1 β but not IL-1ra.

Expression of both type I and type II IL-1 receptors is regulated to control inflammation and immune responses. Dexamethasone, PGE₂ and cytokines with known anti-inflammatory properties, such as IL-4, IL-10, IL-13 and TGF β , can increase receptor expression and shedding from cell membrane. The extracellular domain of both type I and type II receptor is shed by activated neutrophils and monocytes and the solubilized shed receptor binds and inhibits IL-1 β functions. Recently, it was shown that vaccinia and cowpox viruses encode a protein with 30% sequence homology to the soluble type II IL-1 receptor. The presence of this protein counteracts the host inflammatory response to these viruses because viruses genetically engineered to lack these genes become less pathogenic.

Signal transduction by IL-1

The role of internalization in signal transduction remains unclear. After IL-1 binding, IL-1 type I receptor is rapidly internalized. This ligand/receptor complex is relatively resistant to biochemical degra-

dation and can subsequently be found associated with the nucleus. The identification of the intracellular signal transduction pathways and second messenger systems for the biological effects of IL-1 remain to be completely determined. Different types of responding cells may utilize diverse signal transduction pathways for IL-1. IL-1 induces the phosphorylation of a number of cellular proteins such as epidermal growth factor receptor and heat shock proteins. Various kinases including protein kinase C (PKC), tyrosine kinase, mitogen-activated protein kinase (MAP kinase), and ceramide-activated kinase are activated by IL-1. Phosphorylation of phospholipase A₂ (PLA₂)-activating protein activates PLA₂, resulting in the release of arachidonic acid from membrane phospholipids. This leads to enhanced cyclooxygenase activity and the production of prostanooids. In T cells, IL-1 stimulates phosphatidylcholine-specific phospholipase C to generate 1,2-diacylglycerol, which is a potent activator of protein kinase C. IL-1 also activates the transcription factors AP-1 and NFκB which bind to the promoter regions of certain genes (IL-6, IL-8, IL-2 receptor, endothelial cell adhesion molecule). IL-1 enhances the transcription of *c-jun* by activating two novel nuclear factors. Recent studies by Mathias and colleagues suggest that IL-1 binding to receptors activates a neutral sphingomyelinase, hydrolyzing sphingomyelin to ceramide. Ceramide then stimulates a ceramide-activated protein kinase that phosphorylates a specific subset of cellular proteins, thereby altering their function.

Inflammatory and immunological effects of IL-1 (Tables 1 and 2)

Biological activities of IL-1 are mostly indirect and the result of induction of a cascade of other mediators. IL-1 is a pleiotropic mediator of the host response to infection and injury. Its biological activities largely overlap with those of tumor necrosis factor α (TNFα) and IL-6. Many of the effects of IL-1 are mediated through its capacity to increase the production of other cytokines, such as granulocyte colony-stimulating factor (G-CSF), GM-CSF, TNFα, IL-6, IL-8 and homologous members of the chemokine family, platelet-derived growth factor (PDGF), and IL-11. In addition, the effects of IL-1 are amplified through the ability of IL-1 to upregulate receptor expression for itself, for the IL-2 receptor α chain, and for the receptors for IFNγ, IL-3 and GM-CSF.

IL-1 stimulates a variety of cells that function as effectors of immune and inflammatory responses. IL-1 promotes the proliferation of T cells by enhancing the production of IL-2 and the expression of IL-2

Table 1 IL-1 effects *in vivo*

Fever and anorexia
Somnolence and slow-wave sleep
Vasodilation, hypotension and shock
Increased acute phase proteins
Decreased hepatocyte cytochrome P450 activity
Cytotoxicity for β islet cell
Neutrophilia
Hypozincemia
Hypoferremia
Hypercupremia
Hypercalcemia
Increased hormone levels: corticosteroids, ACTH, CRF
Increased insulin and glucagon
Increased heart rate
Endothelial cell activation
Neutrophil accumulation at inflammatory sites
Bone resorption
Cartilage proteoglycan release
Increased Na excretion
Protection against hyperoxic lung injury
Radioprotection
Bone marrow cell cycling
Induction of circulating CSFs
Adjuvant effect
Increased NK activity
Resistance to bacterial infection
Antitumor immunity
Increased tumor metastasis

receptors on T cells. IL-1 augments antigen-induced T cell proliferative and functional responses partly because IL-1 coinduces major histocompatibility complex (MHC) class II expression on antigen-presenting cells. IL-1 also induces the production of IL-6 and TNFα. Recently, Lenardo and colleagues showed that IL-1 production within the thymic microenvironment induces IL-2 receptor α chain expression on early immature thymocytes. Thus, IL-1 is required for thymocyte maturation and CD4⁺CD8⁺ differentiation. The normal thymic development seen in knockout mice that lack the IL-1 type I receptor therefore may be based on compensatory pathways.

IL-1 also promotes B cell development as evidenced by the induction of κ light chain synthesis in pre-B cells. IL-1 augments B cell proliferation, surface IgM expression and antibody production. However, knockout mice that lack the IL-1 type I receptor have normal serum immunoglobulin levels and a normal immune response. IL-1 acts on monocytes and neutrophils, inducing secretion of several cytokines, including IL-8 and IL-1 itself. IL-1 is reported to prolong the survival of neutrophils *in vitro*.

IL-1 participates in the recruitment of leukocytes to inflammatory sites by inducing adhesion molecules (ICAM, ELAM and VCAM) on vascular endothelium and a number of chemokines that attract

Table 2 IL-1 effects *in vitro*

Target cell	Activity
T cell	Induction of IL-2, IL-4, IL-5, IFN γ , IL-2R Potentiation of T cell activation Contributes to thymic development Induction of chemokines
B cell	Induction of IL-6 Enhanced B cell proliferation Potentiation of antibody production
Monocytes/ macrophages	Induction of IL-1, IL-6, IL-8, TNF, GM-CSF, PGE $_2$ and IFN γ receptor Potentiation of cytotoxicity Induction of chemokines
NK cells	Augmentation of cytotoxicity
Neutrophils	Priming
Eosinophils	Degranulation
Dendritic cells	Increased T cell activation
Epithelial cells	Comitogenic Induction of collagen IV
Endothelial cells	Induction of IL-1, IL-6, IL-8, TNF and GM-CSF Induction of procoagulant activity Upregulation of adhesion molecules
Fibroblasts	Induction of IL-1, IL-6, IL-8, TNF and GM-CSF Stimulation of proliferation Induction of PGE $_2$ and collagenase
Synoviocytes	Synthesis of PGE $_2$ and collagenase Induction of hematopoietic growth factors
Chondrocytes	Degradation of proteoglycan Induction of PGE $_2$, collagenase and plasminogen activator
Osteoclasts	Increased proliferation and bone resorption
Osteoblasts	Decreased alkaline phosphate levels
Hepatocytes	Decreased cytochrome P450 and C3
Adipocytes	Decreased synthesis of lipoprotein lipase
Tumor cells	Cytostasis

leukocytes. Other mediators such as IL-1, IL-6, prostanooids, platelet-activating factor and procoagulant factor (tissue factor) are also produced by endothelial cells in response to IL-1.

Other biological activities of IL-1

IL-1 is an important regulator of hematopoiesis, although the phenotype of IL-1 β -deficient mice is remarkably normal. IL-1 induces the production of CSF by bone marrow stromal cell and receptors for CSF. Thus IL-1 synergizes with CSF to stimulate growth of early hematopoietic bone marrow progenitor cells and can counteract the myelosuppressive effects of radiotherapy and chemotherapy. The latter effect is mediated partly through the induction of mitochondrial manganese superoxide dismutase

activity that scavenges potentially toxic superoxide radicals.

IL-1, an endogenous pyrogen, acts on the fever center and also stimulates the hypothalamus to produce corticotropin-releasing hormone (CRH), resulting in the release of adrenocorticotrophic hormone (ACTH) from the pituitary. IL-1 can also directly stimulate pituitary ACTH release. This activation of the HPA axis culminates in induction of the production of glucocorticoids by the adrenals. Glucocorticoids act as a negative feedback regulator by suppressing the production of IL-1 and upregulating both type I and type II IL-1 receptors. IL-1 also inhibits the release of both gonadotropin-releasing hormone and luteinizing hormone (LH), as well as thyroid-stimulating hormone (TSH) and decreases plasma thyroid hormone.

IL-1 is postulated to play a major role in destructive joint disease such as rheumatoid arthritis. It regulates bone resorption by inducing metalloprotease secretion by chondrocytes, resulting in cartilage breakdown and proteoglycan release. IL-1 stimulates fibroblast proliferation and secretion of collagenase, IL-6, IL-8 and G-CSF. It induces cyclooxygenase synthesis and hence prostaglandin release from fibroblasts, but suppresses expression of mRNA for matrix proteins.

IL-1 can have antitumor as well as tumor growth promoting effects. IL-1 has been shown by Onozaki and coworkers to act both as an *in vitro* cytostatic and a cytotoxic agent for a number of tumor cell lines. This activity is associated with inhibition of ornithine decarboxylase activity by IL-1. IL-1 increases natural killer (NK) cell activity and T cell-dependent tumor immunity *in vivo*. Fibrosarcoma tumor cell lines transfected to overexpress IL-1 α have been shown by Apte and colleagues to be more readily rejected and to induce the development of immune resistance upon rechallenge. However, systemic administration of IL-1 has been reported to promote the development of tumor metastases in some animal models. Thus under some circumstances IL-1 appears to promote tumorigenesis.

Therapeutic effects of IL-1 inhibitors

Many of the biological effects of IL-1 are similar to those observed after a severe infection (see Table 1). As a mediator produced in response to microbial invasion, IL-1 will induce fever, myalgia, somnolence, vasodilation and shock, cause bone resorption, induce muscle proteolysis, and induce synthesis of acute phase proteins such as C-reactive protein, serum amyloid A, and fibrinogen by hepatocytes. IL-1 causes a decrease in plasma zinc and iron, which

in turn inhibits growth of virulent bacteria. IL-1 also induces chemokines that are responsible for neutrophil and macrophage emigration to sites of injury, all to arm the host against pathogens. Recent reports of the acquisition of soluble IL-1 type II receptors and inhibitors of ICE by certain viruses underscores the importance of IL-1 in host defense.

IL-1 has been implicated *in vivo* in the pathogenesis of a variety of acute and chronic inflammatory diseases such as septic shock, rheumatoid arthritis and atherosclerosis. Synovial fluids contain IL-1, which acts as a potent stimulator of cartilage resorption. Synovial tissue macrophages also produce high levels of IL-1 β followed by IL-1ra. Endogenously produced IL-1ra levels may be a normal response to limit the proinflammatory, pathogenic effects of IL-1.

A number of naturally occurring inhibitors of IL-1 are present in serum. PGE₂ suppresses the synthesis and release of IL-1. CRH inhibits IL-1-induced anorexia, sleep and prostaglandin synthesis. Corticosteroids suppress expression of IL-1 mRNA. TGF β , IL-4, IL-10 and IL-13 inhibit IL-1 production. β -melanocyte-stimulating hormone inhibits the synthesis and activities of IL-1.

The role of the natural antagonist, IL-1ra, in normal physiology remains to be understood. IL-1ra can block IL-1-induced T cell proliferation, although 50% inhibition of IL-1 biological effects *in vitro* requires a 10- to 500-fold excess amount of IL-1ra. IL-1ra does not alter *in vitro* T cell proliferative responses to mitogens, antigens or alloantigens. IL-1ra blocks LPS-induced IL-8 production in mononuclear cells. IL-1ra also decreases IL-2 receptors and secretion of IL-1 α , IL-1 β , IL-2 and TNF in these cells *in vitro*. Several studies have shown that inhibition of IL-1ra by neutralizing antibodies results in considerable exacerbation of inflammatory diseases. Thus, IL-1ra plays a role in downregulating *in vivo* inflammatory reactions. In animal models, IL-1-induced hypotension can be inhibited by pretreating the animals with large doses of IL-1ra. However, the large amounts of IL-1ra (10 000-fold molar excess, 2.5 g day⁻¹ estimated for human use) required to counteract IL-1-mediated effects reduces the clinical usefulness of IL-1ra. Thus, IL-1ra as yet has no significant therapeutic potential in human phase III clinical trials for sepsis. However, the demonstrated proinflammatory effect of suppressing IL-1ra *in vivo* suggests that improved delivery systems may make IL-1ra more effective.

Other approaches to block IL-1-mediated responses include the use of IL-1-specific antibodies, IL-1 receptor-specific antibodies, soluble IL-1 receptors and inhibitors of ICE.

Gene deletion of IL-1

Despite the plethora of IL-1 activities, knockout mice that are defective in the production of IL-1 α or IL-1 β or in the expression of IL-1 type I receptor are viable and show only relatively limited phenotypic deficiencies. Kluger and coworkers showed resistance to fever induction in IL-1 β -deficient mice. Studies by Dinarello and colleagues indicated that IL-1 β -deficient mice have an impaired acute-phase response to a local injection of turpentine although systemic administration of LPS gave a normal inflammatory response in these mice. This normal response to LPS is probably due to *in vivo* compensatory mechanisms that correct for the lack of IL-1 signals in IL-1 knockout mice and to the redundancy in the activities of IL-1, TNF α and IL-6.

In summary, IL-1 plays a central role in regulating immune responses, often through the induction of other mediators and cytokines. IL-1 is the only cytokine for which a natural endogenous inhibitor with specificity exists, IL-1ra, to counteract its biological effects. An additional natural mechanism to moderate the effects of IL-1 is suggested by adrenalectomy in animals, which results in a more pronounced inflammatory response, indicating that normal adrenal activity buffers IL-1 activity. Thus, multiple mechanisms such as the shedding of IL-1 receptors, corticosteroids and IL-1ra exist naturally to carefully regulate the levels and activities of IL-1.

Interleukin 2 (IL-2) was one of the first interleukins to be characterized. Initially called T cell growth factor (TCGF), its activity was detected in the supernatant of mitogen-stimulated peripheral blood lymphocytes. It was immediately used for the culture of T lymphocytes *in vitro*. After complete molecular characterization (purification and cloning) and identification of its receptor, IL-2 was quickly recognized as a central factor in controlling the immune response. Large quantities of IL-2 have been produced and used in clinical trials aimed at stimulating the immune system, particularly against tumors.

Molecular characterization of IL-2

IL-2 belongs to the hematopoietin family which includes growth hormone, prolactin, IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-10, IL-11, IL-13, IL-15, GM-CSF, etc. The IL-2 gene, located on chromosome 4 (q26-q27), contains four exons coding for a 153 amino acid precursor including a 20 amino acid leader sequence. Human IL-2 contains only one O-glycosylation site (Thr3); glycosylation at this site is heterogeneous but does not affect biological activity. The three-dimensional structure of IL-2 is essentially composed of four α helices (A, BB', C and D) connected by three loops (Figure 1). A disulfide bridge between Cys58 and Cys105 is necessary for the bioactivity of the molecule. The regions of the molecule involved in binding to the three chains of the

IL-2 receptor (α , β and γ) have been identified. IL-2/IL-2R β interactions mainly involve helix A and IL-2/IL-2R γ interactions involve helix D, whereas IL-2/IL-2R α interactions mainly involve the loop between helix A and helix BB'.

IL-2 production

IL-2 is produced by CD4 T lymphocytes. During the immune response CD4 lymphocytes differentiate into T_H1 and T_H2 functional subsets. This pattern of differentiation is very clear in the mouse, where T_H1 lymphocytes produce IL-2 and interferon γ , and T_H2 lymphocytes produce IL-4, IL-5 and IL-6. In humans, however, this functional dichotomy of CD4 lymphocytes is less distinct.

Resting CD4 lymphocytes do not produce IL-2. Two types of signals (signal 1 and signal 2) induce the production of IL-2. Signal 1 is dependent on the binding of the T cell receptor (TCR) to the antigen/MHC (major histocompatibility complex) complex. It can be mimicked by antibody against the TCR or by some lectins. Signal 2 follows the binding of T cell surface molecules such as CD28 or CTLA-4 to B7-2 and B7-1 present on the surface of the antigen-presenting cells. Maximum production of IL-2 occurs when both signals are present. Other costimulating molecules (cell surface antigens, cytokines) are also involved in the optimal production of IL-2. Alone, signal 1 induces an anergy of the T_H lymphocytes. This anergic state is characterized by the inability to react to a second antigenic signal. IL-2 can replace signal 2 and prevent the induction of an anergic state.

Some CD8 clones can produce small amounts of IL-2. Under certain conditions B lymphocytes are also able to produce IL-2: Epstein-Barr virus (EBV)-infected lines produce IL-2 as well as normal B lymphocytes cultured in the presence of anti-CD40 monoclonal antibodies (mAb) and IL-4 and subsequently stimulated by phorbol esters and calcium ionophore.

The transcription of the IL-2 gene is highly regulated by a 300 bp promoter. This promoter region can bind many transcription factors. Among them two NFAT factors (p and c) and AP-1 (heterodimer of fos and jun) are essential.

Figure 1 Structure of interleukin 2.

Targets of the stimulatory activity of IL-2

Most cells of the immune system can express the high-affinity (IL-2R α , β , γ) or the intermediate-affinity (IL-2R $\beta\gamma$) IL-2 receptors, either spontaneously or after stimulation. Consequently IL-2 has many targets (Figure 2).

T lymphocytes

The primary role of IL-2 is to expand activated CD4 and CD8 lymphocytes. On T_H1 cells IL-2 acts in an autocrine fashion. IL-2 also induces the growth of T_H2 and CD8 lymphocytes as a paracrine factor. IL-2 has no influence on the T_H1/T_H2 balance. On CD8 lymphocytes IL-2 stimulates cytotoxic activity. After stimulation T lymphocytes produce many cytokines and express the corresponding receptors. However IL-2 remains the main cytokine controlling the proliferative response of CD4 lymphocytes. The proliferation of purified CD4 lymphocytes stimulated by anti-CD3 is completely neutralized by anti-IL-2 monoclonal antibodies.

B lymphocytes

Activated B lymphocytes express the high-affinity IL-2 receptor and respond to IL-2. Under these conditions they proliferate intensively and produce immunoglobulins of the IgM, IgG and IgA isotypes. Different stimulations can induce the susceptibility of B lymphocytes to IL-2. Experimentally anti-Ig, or lipopolysaccharides (LPS) are good stimulators. Physiologically, in the context of T/B collaboration T_H1 lymphocytes (or T_H1-like in humans) may induce an intense proliferation and differentiation of the B lymphocyte population. Unlike IL-4, IL-5 and transforming growth factor β (TGF β), IL-2 does not exert an influence on isotype selection.

Natural killer (NK) cells

All NK cells are spontaneously sensitive to IL-2. In the majority of these cells IL-2 can stimulate cytotoxic activity without stimulating NK cell proliferation. In rare NK cells, expressing the high-affinity IL-2R, IL-2 stimulates both cytotoxic and proliferative responses. NK cells play a dominant role as the first defense barrier against viral infections and tumor growth.

Monocytes

IL-2 spontaneously stimulates the killing of tumor cells and bacteria by monocytes. Interferon γ (IFN γ) and LPS stimulate the appearance of high-affinity IL-2R on the surface of monocytes and therefore increase sensitivity to IL-2. During IL-2 stimulation monocytes produce a large array of mediators such as H₂O₂, prostaglandin E₂ (PGE₂), thromboxane B₂, and tumor necrosis factor α (TNF α). These products may be responsible for the side-effects observed during IL-2 therapy.

Granulocytes

Neutrophils are also sensitive to IL-2. Their anti-fungal activity is greatly enhanced by IL-2, perhaps because of the production of lactoferrin and TNF α by these cells.

IL-2 is a pleiotropic cytokine with proinflammatory activity both on the nonspecific arm of the immune system (NK cells, monocytes) and on the specific response generated by T and B cells.

IL-2 in the negative control of lymphocyte proliferation

Autoimmunity in IL-2-deficient animals

The precise role of IL-2 *in vivo* is not well understood. An important tool for studying this question

Figure 2 Interleukin 2 immune activity.

is provided by gene knockout mice produced after homologous recombination. In IL-2^{-/-} animals the ontogeny of the immune system is not dramatically affected, as demonstrated by the normal development of lymphoid organs and the presence of the major lymphocyte subsets. However IL-2^{-/-} animals have an overproduction of lymphocytes, which is morphologically reflected by lymphoid organ hyperplasia. This observation is surprising since IL-2 was first described as a T cell growth factor.

As expected, the immune response of IL-2^{-/-} mice is abnormal at the T and B cell level. The *in vivo* cytotoxic response against viruses is reduced, although *in vitro* cytotoxic responses can be restored by addition of IL-2.

The most striking observation made with IL-2^{-/-} animals is the development of an autoimmune syndrome. The intensity of the disease is dependent both on environmental factors and the genetic background of the animals. Fifty per cent of IL-2^{-/-} mice in a 129/01a × C57B16 genetic background die of autoimmune hemolytic anemia before 9 weeks of age. All animals that survive past 10 weeks of age develop an inflammatory bowel disease comparable to ulcerative colitis in humans. Mice kept in germ-free conditions do not develop the disease. The data obtained with IL-2^{-/-} mice as well as with IL-2Rα^{-/-} and IL-2Rβ^{-/-} animals indicate that there may be a defect in cell apoptosis in these animals.

IL-2 in the control of apoptosis

Shortly after antigen recognition an autocrine loop is established based on the coexpression of IL-2 and the IL-2R by T cells, which functions to drive responding cells through the cell cycle. IL-2 also promotes the survival of T cells in culture, presumably by inducing the expression of Bcl-2, a protein that protects cells from passive apoptotic cell death. *In vivo* this mechanism may be related to the persistence of some memory cells.

On the other hand, several recent studies have demonstrated that clonal expansion of activated T cells can be controlled by the induction of programmed cell death of some activated lymphocytes. The major pathway of this activation-induced cell death (AICD) involves the interaction of Fas expressed by activated T and B cells and Fas ligand produced by a subset of activated T cells. IL-2 is a critical determinant of AICD: addition of IL-2 to stimulated T cell clones increases AICD whereas anti-IL-2 antibodies reverse the deletion of these cells. The effect of IL-2 on AICD may be explained by the acquisition of susceptibility to Fas-mediated

apoptosis after treatment with IL-2, but not by increased Fas expression.

IL-2-dependent immune responses are transient since IL-2-induced activation and clonal expansion is followed by AICD. Furthermore IL-2 appears to be critical for triggering a mechanism that regulates self-tolerance and prevents pathological autoimmunity.

Clinical aspects

The major clinical use of IL-2 to date has involved tumor immunology. The potential for IL-2 as a cancer treatment is based on activation of cells which are cytotoxic for the tumor, and some success has been obtained with renal cell carcinoma and metastatic melanoma. However the use of IL-2 is limited by various side-effects. To circumvent these difficulties lymphokine-activated killer (LAK) cells as well as tumor-infiltrating lymphocytes (TILs) have been tested after *in vitro* activation by IL-2. Local delivery of IL-2 to the tumor site and genetic modification of the tumor cells by the IL-2 gene are currently under clinical trial.

Coupled to toxin, IL-2 can be used as an immunosuppressive agent. IL-2 fragments coupled to *Pseudomonas* exotoxin (IL-2-PE40) or diphtheria toxin (IL-2-DAB486) have been studied. They inhibit graft rejection in animals and were found to have beneficial effects on rheumatoid arthritis. Drugs which limit the production of IL-2 (cyclosporine and FK506) are classically used during graft transplantation in humans.

IL-2 has been used in AIDS (acquired immune deficiency syndrome) patients as an immunostimulatory agent able to limit the effects of CD4 depletion. After IL-2 injection and under some clinical conditions, IL-2 treatment is followed by an increase of the CD4 count without affecting the viral load.

Interleukin 2 (IL-2) is a growth factor for T cells and natural killer (NK) cells, where it induces G_1 - to S-phase progression, and a differentiation factor for B cells, where it induces immunoglobulin secretion. The high-affinity IL-2 receptor (IL-2R) is composed of three distinct chains, designated α , β and γ . Intracellular signaling is initiated by ligand-induced heterodimerization of the IL-2R β and γ chains, which results in the activation of multiple intracellular kinases, including members of the Janus kinase (JAK) family. These biochemical events induce expression of a variety of target genes with mitogenic and differentiative functions.

Structure and expression of the IL-2R

Subunit composition of the three IL-2R complexes

The IL-2 molecule has a four α helix bundle structure characteristic of many cytokines and, from molecular modeling and mutational studies, is thought to contain distinct binding sites for each of the three IL-2R chains. Depending on which subunits are expressed by a cell, three distinct forms of the IL-2R can be detected. The high-affinity IL-2R (K_d 5–10 pM) is found on activated lymphocytes and consists of an $\alpha:\beta:\gamma$ trimeric complex (Figure 1). As this receptor complex generates a proliferative response at low concentrations of IL-2, it is thought to represent the physiologically relevant IL-2R for *in vivo* responses. IL-2R α alone can form a low-affinity receptor for IL-2 (K_d 5–10 nM), however this complex fails to signal. Finally, the human IL-2R β and γ chains together form an intermediate affinity receptor (K_d 0.5–1 nM) which is found on NK cells, macrophages and resting T cells and can signal in the presence of high concentrations of IL-2. In contrast to the human receptor, however, it remains controversial whether the murine IL-2R β and γ chains form a functional intermediate-affinity IL-2R.

On activated lymphocytes coexpressing all three IL-2R chains, IL-2R α and β appear to preassociate as a stable heterodimer in the absence of ligand. IL-2 is thought to bind first to this $\alpha:\beta$ heterodimer and

Figure 1 Schematic overview of the high-affinity interleukin-2 receptor complex, including the receptor chains, downstream signaling components and target genes (boxes). Also shown are two tyrosine residues (Tyr³³⁸ and Tyr⁵¹⁰) on IL-2R β that are implicated in mitogenic signaling. Arrows indicate established connections between signaling proteins and target genes. Tyr³³⁸ is required for SHC-mediated activation of the Ras/MAP kinase pathway, which is thought to regulate expression of *c-fos* and *c-jun*. Tyr⁵¹⁰ mediates activation of the transcription factor STAT5, which is implicated in the regulation of the IL-2R α , oncostatin M (*osm*) and *cis* genes.

to subsequently recruit the γ chain. IL-2 binds the high-affinity receptor complex with a rapid on-rate ($t_1 \sim 35$ s), contributed by IL-2R α , and remains bound due to a slow off-rate (t_2 250–300 min), con-

tributed primarily by IL-2R β . Intracellular signaling is initiated by IL-2-induced heterodimerization of the cytoplasmic domains of the β and γ c chains (see below), which is followed by rapid internalization of the ligated receptor complex.

The IL-2R α chain

The α chain of the IL-2R was the first to be defined at a molecular level due to its unique ability to independently bind IL-2. IL-2R α (also known as Tac antigen or CD25) is a glycoprotein of approximately 55 kDa and contains an extracellular domain of 219 amino acids, a transmembrane domain of 19 residues and a cytoplasmic domain of only 13 residues. The chain shares sequence homology with the α chain of the IL-15 receptor, particularly within an extracellular region known as the sushi domain, which contains residues required for ligand binding. Resting T cells do not express detectable amounts of IL-2R α and consequently are unable to bind IL-2 with high affinity. However, antigen stimulation rapidly induces expression of the IL-2R α gene by activating a variety of transcription factors, including NF κ B, c-Rel, serum response factor, Elf-1 and HMG-I(Y), that bind to proximal sites in the IL-2R α promoter. IL-2 itself can also further upregulate the expression of IL-2R α by activating STAT5 and other transcription factors that bind sites 1–4 kb upstream of the transcriptional start site.

Antibodies to IL-2R α (anti-Tac) are being evaluated clinically as T cell-specific immunosuppressants for the treatment of graft-versus-host disease. In addition, anti-Tac conjugated to yttrium-90 is being investigated for the treatment of T cell lymphomas.

The IL-2R β chain

The mature β chain of the IL-2R is a glycoprotein of approximately 75 kDa and contains an extracellular domain of 214 amino acids, a transmembrane domain of 25 residues and a long cytoplasmic domain of 286 residues. IL-2R β belongs to the hematopoietic receptor superfamily by virtue of 1) conserved cysteine residues and a Trp-Ser-Pro-Trp-Ser motif in the extracellular domain, residues that are required for ligand binding, and 2) Box 1 and Box 2 motifs in the membrane-proximal cytoplasmic region that are essential for mitogenic signaling and for association with Janus tyrosine kinases (JAKs).

IL-2R β is generally expressed at low levels on resting T cells and is modestly upregulated by antigen stimulation. It is constitutively expressed at moderate to high levels on NK cells and macrophages. As the IL-2R β chain is also a component of one

form of the IL-15 receptor, it is sometimes referred to as IL-2R β c, for common IL-2R β chain.

The γ c chain

The γ c chain was originally identified as the third subunit of the IL-2R but shortly thereafter was found to also be a component of the receptors for IL-4, IL-7, IL-9 and IL-15, hence the designation γ c (for common γ chain). The mature γ c chain is a glycoprotein of approximately 64 kDa with an extracellular domain of 232 residues, a transmembrane domain of 29 residues, and a cytoplasmic domain of 86 residues. The extracellular domain contains conserved cysteine residues and a Trp-Ser-Glu-Trp-Ser motif, qualifying γ c also as a member of the hematopoietic receptor superfamily. The membrane-proximal cytoplasmic region of γ c shares homology with the α chains of the IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF) receptors, which are additional members of this superfamily. This region of γ c also shows partial resemblance to an SH2 domain, but is unlikely to function as such since it lacks most of the residues necessary for binding phosphotyrosine.

Consistent with the involvement of γ c in diverse cytokine receptor complexes, the chain is expressed constitutively by multiple hematopoietic cell types, including macrophages and T, B and NK cells. The γ c gene is located on the X chromosome and constitutes the genetic locus of X-linked severe combined immune deficiency (X-SCID; see below).

IL-2R signal transduction

Although all three chains of the IL-2R are required for high-affinity binding of IL-2, experiments with chimeric receptor chains containing alternative extracellular domains have demonstrated that ligand-induced heterodimerization of the cytoplasmic domains of the β and γ c chains is necessary and sufficient for intracellular signaling. Thus, the role of the α chain appears to be limited to conferring high-affinity binding of IL-2 to the receptor complex. The membrane-proximal cytoplasmic regions of IL-2R β and γ c associate noncovalently with the tyrosine kinases JAK1 and JAK3, respectively (Figure 1). IL-2R β has been shown to also bind and activate the tyrosine kinases Lck, Fyn and Syk. In T cells, heterodimerization of IL-2R β and γ c induces rapid catalytic activation of JAK1 and JAK3 and rapid tyrosine phosphorylation of multiple substrates including JAK1, JAK3, IL-2R β , γ c, the transcription factor STAT5, the adapter molecules SHC and GRB-2, the tyrosine phosphatase SHP-2, the regulatory subunit (p85) of phosphatidylinositol 3-kinase (PI3K), and the MAP

kinase ERK-2 (Figure 1). Signaling results in the induction of multiple target genes associated with proliferation, including *c-myc*, *c-fos*, *c-jun*, and *bcl-2*, as well as a number of nonmitogenic genes, including IL-2R α and oncostatin M (osm).

Activation of the tyrosine kinase JAK3 is a critical early event in IL-2 signaling, as disruption of JAK3 catalytic activity abrogates almost all of the above tyrosine phosphorylation events and virtually eliminates the mitogenic response. The few JAK3 kinase-independent events described to date include low-level tyrosine phosphorylation of IL-2R β and SHP-2, induction of the proto-oncogene *bcl-2* and prolongation of cell viability. By contrast, disruption of JAK1 activity is reported to have little effect on mitogenic signaling. The critical role of JAK3 catalytic activity indicates that tyrosine phosphorylation of one or more intracellular substrates is essential for mitogenesis. Indeed, mutation of all cytoplasmic tyrosine residues of IL-2R β to phenylalanine eliminates the mitogenic response in the face of normal activation of JAK1 and JAK3. Restoration of either Tyr338, which is required for SHC phosphorylation, or Tyr392 or Tyr510, which can mediate activation of STAT5, rescues the proliferative response in lymphocytes. This suggests that the mitogenic component of the IL-2R signal involves JAK3-dependent tyrosine phosphorylation of IL-2R β , followed by the recruitment and phosphorylation of SHC, STAT5 or possibly other downstream signaling molecules. Consistent with this model, T cells transformed by the human retrovirus HTLV-I (human T lymphotropic virus type I) demonstrate a correlation between IL-2-independent growth and constitutive activation of JAK3 and STAT5.

Aside from tyrosine kinases, several other enzymatic activities are associated with IL-2R signaling. Components of the Ras/MAP kinase pathway are activated in response to IL-2, and are thought to regulate the expression of *c-fos* and *c-jun*. The lipid kinase PI3K is also activated by IL-2, although the role of this molecule in signaling remains undefined. The IL-2R also induces catalysis of glycosylphosphatidylinositol through activation of an unidentified enzyme. Finally, the novel protein serine kinase mTOR (mammalian target of rapamycin) has been implicated in IL-2R signaling, as rapamycin, a pharmacological inhibitor of mTOR, greatly reduces IL-2R-mediated proliferative responses. Rapamycin acts in part by delaying the onset of *bcl-2* expression induced by IL-2 and by preventing the downregulation of p27^{kip1}, an inhibitor of G₁- to S-phase progression. Rapamycin is currently being evaluated clinically as an immunosuppressant.

Genetic disruption of IL-2R subunits

As IL-2 is required to maintain the growth and viability of T cells *in vitro*, one might expect disruption of the genes encoding IL-2 or any of the IL-2R subunits to significantly impair T cell development or expansion. However, mice lacking the IL-2, IL-2R α or IL-2R β genes demonstrate apparently normal development of T, B and NK cells and, rather than showing reduced lymphocyte expansion, frequently demonstrate hyperproliferation of lymphocytes and development of T cell-dependent autoimmune disorders such as hemolytic anemia and inflammatory bowel disease. In contrast, $\gamma c^{-/-}$ mice show severely impaired lymphocyte development, consistent with the involvement of γc in other cytokine receptor complexes. Indeed, the IL-7 receptor utilizes γc and has been shown to be essential for B cell and thymocyte development. Collectively, these results suggest that in the absence of IL-2 or a functional IL-2R, other γc -dependent cytokine receptors can mediate lymphocyte development and expansion *in vivo*. However, an intact IL-2R signaling pathway appears to be required to limit the magnitude of immune responses and prevent the development of certain forms of autoimmunity, perhaps reflecting a role for IL-2 in the regulation of antigen-induced cell death.

In humans, the γc gene represents the locus of X-SCID, a syndrome characterized by a lack of functional T and B cells. Interestingly, patients with mutations in the JAK3 locus suffer from a syndrome very similar to X-SCID, underscoring the critical role of JAK3 in γc -mediated signaling. Genetic therapies are being developed for these immunodeficiencies based on retrovirus-mediated transduction of the wild-type γc or JAK3 genes into the hematopoietic stem cells of patients.

INTERLEUKIN 3

John W Schrader, The Biomedical Research Centre, UBC, Vancouver, Canada

Tissue culture systems for generating *in vitro* cells of hematopoietic origin were established in the early 1960s by Ginsberg and Sachs. The cells were mast cells and they appeared in cultures of murine thymocytes. In hindsight, it is likely that the generation of these mast cells resulted from the release of interleukin 3 (IL-3), now known to be a potent mast cell growth factor, from activated T cells. Activation of the T lymphocytes probably occurred as a result of a mixed lymphocyte reaction, as the mice used as sources of the thymocytes were not inbred. Sachs and Pluznick, and Metcalf and Bradley in Australia, went on to develop the colony assays that allowed single bone marrow progenitor cells to grow into small colonies of differentiated cells under the influence of soluble factors termed colony-stimulating factors (CSFs).

At the end of the 1960s, Metcalf and his colleagues noticed, using the colony assay, that a murine myelocytic leukemia, WEHI-3B, released activities which stimulated the growth from bone marrow progenitors of colonies with a distinctive morphology, now known to result from the action of IL-3. However, the recognition of IL-3 as a distinct hematopoietic factor, affecting multiple hematopoietic cell lineages, had to wait until the late 1970s and came simultaneously from laboratories studying quite different

phenomena. Dexter and colleagues observed that long-term cultures of mouse bone marrow occasionally gave rise to lines of cells which were dependent for their growth on a factor that was released by the myelomonocytic tumor WEHI-3B, but was distinct from granulocyte-macrophage colony-stimulating factor (GM-CSF). At the same time, a number of groups (Aaronson, Hasthorpe, Nabel, Moore, Razin, and Schrader) observed that cells from mouse spleen, fetal liver or bone marrow that had been cultured in the presence of medium that had been conditioned by activated T cells, or by WEHI-3B, gave rise to homogeneous populations of cells with the characteristics of mast cells. In another distinct line of research, Ihle observed that activated T cells and WEHI-3B released a factor that stimulated increased levels of an enzyme 20 α -hydroxysteroid dehydrogenase, thought at that time to be an exclusive marker of T lymphocytes.

Pleiotropic effects of IL-3 on hematopoietic cells

Biochemical purification demonstrated that the activities studied by these groups all resided in a single molecule that had gone under many names reflecting its multiple activities: namely, IL-3, mast

cell growth factor, P cell stimulating factor, panspecific hematopoietin, multicolony-stimulating factor, CSF2a, CSF2b, hematopoietic growth factor, burst-promoting activity, histamine-producing cell-stimulating activity, Thy-1 inducing factor, and colony-forming units (CFUs) stimulating activity. This molecule stimulated the growth of colonies of mast cells, neutrophils, macrophages, eosinophils, megakaryocytes and erythroid progenitors, and colonies containing a mixture of these cell types. Its presence in bone marrow cultures also permitted the survival of CFUs and cells that could repopulate the lymphoid compartment of irradiated mice, the latter observation pointing to a direct or indirect effect on pluripotential hematopoietic stem cells.

The role of IL-3 in the generation of lymphocytes continues to be the source of some controversy. IL-3 appears to be capable of stimulating the growth of early B cell progenitors, but only in the absence of myeloid cells, which appear to inhibit the growth of B cell progenitors. At present, it would seem reasonable to conclude that IL-3 is active on all of the cell lineages derived from pluripotential hematopoietic stem cells, with the exception of those giving rise to T lymphocytes.

Structure

Structurally, IL-3 is a member of a family of cytokines that includes the CSFs, many interleukins, and other cytokines. These share a characteristic three-dimensional structure and have been termed '4-helix-bundle cytokines'. IL-3 is a polypeptide of 140 amino acids in the mouse and 133 in the human. Although there is little amino acid homology between IL-3 and other peptide regulatory factors, IL-3 does share with GM-CSF, IL-2, erythropoietin, and certain other cytokines, a common motif of Ala-Pro at the N terminus. The functional significance of this motif is unclear; it can be deleted without affecting the ability of IL-3 to activate its receptor.

The genes for IL-3 and GM-CSF have broad structural similarities and are closely linked, consistent with their origin from a common ancestor. The genes for IL-3 in the human and mouse have diverged very considerably, the amino acid sequences being only 29% homologous. Rat IL-3 is only about 70% homologous with mouse IL-3, and rat, mouse and human IL-3 do not act across these species barriers. Similarities between human and mouse genes are in fact greater in the noncoding sequences.

Structure-function studies of the murine IL-3 molecule have shown that significant portions of the N- and C-termini can be deleted without affecting bioactivity *in vitro*. IL-3 became the first protein of

its size to be successfully chemically synthesized in biologically active form using automated peptide synthesis.

IL-3 is heavily glycosylated and runs on SDS-PAGE gels as a series of glycoforms with M_r ranging from 22 000 to 34 000, compared with 14 000 for the nonglycosylated peptide. The function of this carbohydrate is completely unknown. It does not seem to be related to the stability of the molecule in the blood and only modestly prolongs its half-life in the plasma. It may play a more subtle role, for example in localization of the molecule in specific sites *in vivo*.

Receptor

IL-3, like most other 4-helix-bundle cytokines, binds to an oligomeric receptor made up of subunits that are members of a family of proteins termed the 'cytokine or hemopoietin receptor superfamily'. IL-3 binds with relatively low affinity to a specific α -chain receptor subunit (IL-3R α). High-affinity binding and signal transduction requires interaction of the IL-3-IL-3R α complex with a larger β -chain receptor subunit. This β chain is shared with the GM-CSF and IL-5 receptors (each of which have a GM-CSF- or IL-5-specific α chain) and is thus termed ' β common' or β_c . In the mouse, the situation is more complex in that the complex of IL-3 and IL-3R α can also interact with an IL-3-specific β chain (AIC-2A or β_{IL-3}), which has resulted from duplication of the β_c gene and itself has low affinity for IL-3.

Binding of IL-3 to the IL-3R α occurs with relatively low affinity and is followed by interaction with a β_c , or, in the mouse, β_{IL-3} , and the formation of a high-affinity complex. The resultant approximation of the cytoplasmic domains of the α and β chains is probably sufficient to activate cytoplasmic tyrosine kinases such as JAK2 kinase, which is known to be activated following binding of IL-3 to its receptor. More complex mechanisms that require the assembly of a larger complex, resulting from recruitment of an additional β chain or of other IL-3-IL-3R α / β chain complexes, however, have not been completely excluded. Interaction of IL-3 with its receptor results in activation of many of the intracellular signaling paths also stimulated by other growth factors. These include activation of Ras and three branches of the MAP kinase family, the ERK-1,2 Map kinases, the JNK/SAPK kinases, and the p38MAP kinases. These in turn activate other kinases, in the case of Erk-1/2, p90RSK and in the case of p38MAP kinase, MAPKAP-2 kinase. The Map family kinases also directly phosphorylate transcription factors such as c-Jun, ATF-2, CREB, E1k-1 and Sap, upregulating

their activity. IL-3 induces upregulation of the expression of genes such as c-myc, c-fos, c-jun, bcl-2 and bclx_L. Phosphatidylinositol 3 kinase is also activated. Activation of the transcription factor STAT5 is a relatively specific consequence of IL-3 stimulation, although it also occurs in response to GM-CSF, and IL-5, and IL-2 and prolactin. When activated by tyrosine phosphorylation and dimerization, STAT5 upregulates expression of a series of genes including those encoding oncostatin-M and Cis, as well as contributing to upregulation of expression of c-fos.

Sources of IL-3

The major physiological sources of IL-3 appear to be T lymphocytes and, in the human, natural killer (NK) cells. IL-3-dependent mucosal mast cells, connective tissue mast cells and eosinophils also produce small amounts of IL-3 when they are stimulated, for example, by crosslinking of antibodies bound to Fc receptors on their surface. IL-3 released during allergic reactions may affect the functions of mast cells and eosinophils as well as those of other cells such as macrophages. There is no evidence that any of the stromal cells of the bone marrow normally produce IL-3.

Physiology of IL-3

An extremely potent molecule, IL-3 is detectable in *in vitro* bioassays in concentrations of 0.1 pM or less. The sensitivity of various target cells to the action of IL-3 varies considerably, probably due to differences in receptor levels. Thus, whereas certain IL-3-dependent mast cell lines, particularly those that have been in culture for many years, are sensitive to subpicomolar concentrations of IL-3 progenitor cells and stem cells may require 10–50-fold higher concentrations for maximal effects and some mature cells, such as macrophages, even higher concentrations.

As is the case with many peptide regulatory factors, it is likely that in many physiological circumstances IL-3 acts in the vicinity of the cell that has produced it. However, when there is relatively massive activation of T lymphocytes, for example in graft-versus-host disease, IL-3 can appear in the bloodstream and act systemically. IL-3 has a relatively short half-life in the blood, of the order of 40 minutes, and is destroyed at sites such as the renal tubule and liver.

Physiologically, IL-3 links activation of T lymphocytes and mast cells to stimulation of the generation of the accessory cells – granulocytes, phagocytes and platelets – which carry out defense and repair

responses. It is thus an important participant in the response of the hematopoietic system to stress.

There is no good evidence that IL-3 is normally present in the blood or indeed is produced in a normal animal that is not undergoing some immunological stimulation. In particular, there is no evidence that bone marrow stromal cells produce IL-3. Thus there are no data to support the view that IL-3 is involved in regulating normal, steady-state hematopoiesis. Mice lacking functional IL-3 genes have no overt phenotype and the hematopoietic system appears to develop normally.

Clinical significance of IL-3

The *in vivo* administration of IL-3 results in all of the phenomena that might be predicted from its activity in tissue culture systems. Thus there is a rapid and dramatic increase in the number of mast cells in tissues such as spleen and also the skin. In the mouse spleen, there are increases in the number of progenitor cells of various lineages and of pluripotent hematopoietic stem cells. In the bone marrow, there is an increase in the frequency of pluripotent hematopoietic stem cells.

IL-3 has synergistic effects with other hematopoietic growth factors such as GM-CSF and there is evidence that the sequential administration of first IL-3, stimulating primitive stem and progenitor cells, and then a factor, such as GM-CSF, that affects specific lineages, will provide maximal stimulation of myelopoiesis. Administration of IL-3 also results in mobilization of hematopoietic stem cells into the blood. The clinical utility of IL-3 has yet to be established. Studies are in progress to determine whether, particularly when used in conjunction with other growth factors such as GM-CSF, IL-3 will enhance the recovery of the bone marrow after procedures such as bone marrow transplantation or chemotherapy.

In the long term, as is the case with many peptide regulatory factors, antagonists may have more clinical significance than the factors themselves or agonists. Animal studies are revealing a variety of disease states – ranging from allergic and infectious diseases to leukemia – where antagonists may have a role to play in therapeutic procedures. For example, antibodies to IL-3 given together with antibodies to IL-4 block the mastocytosis seen in parasitized rats. Administration of IL-3 results in accelerated IgE responses and expulsion of *Trichinella spiralis*, and appears to promote the production of IL-10 and IL-13, cytokines which promote T_H2 responses. Thus IL-3 antagonists may find a useful role in allergic diseases or asthma. Antibodies to IL-3 and GM-CSF

have also been shown to block the pathogenic accumulation of macrophages in the brain of mice suffering from cerebral malaria. In leishmaniasis in mice, there is evidence that IL-3 exacerbates the disease process and antibodies to IL-3 favor disease regression. These findings may reflect an antagonistic activity of IL-3 on the action of interferon γ , which is known to activate mechanisms that kill intracellular leishmania.

The investigation of IL-3 has provided insights into the role of autostimulatory production of growth factors in tumorigenesis. It is now clear that WEHI-3B, the monocytic tumor from which IL-3 was originally purified, produces IL-3 as a result of pathological activation of one IL-3 gene by insertion of viral DNA. Moreover, early passages of WEHI-3B appeared to be dependent on this IL-3. In other experiments, a spontaneous variant of an IL-3-dependent cell line was isolated through its ability to survive and grow in the absence of IL-3. This property of the cell was shown to be due to autogenous IL-3. Significantly, unlike the parental line, when injected into a mouse this variant cell gave rise to a disseminated leukemia. These leukemic animals had detectable amounts of IL-3 in their serum. A number of other such examples in which the growth of leukemic cells depends on the production of autostimulatory growth factor, such as IL-3 or GM-CSF, have now been uncovered. Antagonism of the action of autostimulatory growth factors can result in death of the leukemic cells. However, the autostimulatory production of IL-3 does not appear to be a significant cause of human malignancy.

Conclusion

Structural analysis of IL-3 and its receptor and the IL-3-specific components of IL-3 signal transduction pathways should ultimately lead to the design of small molecules that can mimic or antagonize IL-3. The capacity of IL-3 to stimulate primitive cells in the hematopoietic system is likely to be an advantage in the design of strategies to stimulate recovery of bone marrow, especially after chemotherapy for cancer or other aplastic diseases of the marrow. In inflammatory diseases, particularly where mast cells

play a key role, such as asthma or allergy, IL-3 antagonists may find a useful role.

Interleukin 3 (IL-3) is a T cell-derived pluripotent hematopoietic colony-stimulating factor required for the survival and proliferation of primitive hematopoietic progenitor cells. It signals target cells through a high-affinity cell surface receptor. The IL-3 receptor was first described on murine bone marrow cells. These cells appeared to express a single high-affinity binding site with a K_d of around 100 pM, and only a few hundred sites per cell. In several murine hematopoietic cell lines however, a low-affinity site ($K_d = 10$ nM) has also been described. Chemical cross-linking studies indicated multiple cross-linked proteins with molecular weights of 140, 120 and 70 kDa. Studies with human hematopoietic cells also described an IL-3 receptor with a K_d of 70–100 pM and about 100–200 sites per cell. Chemical cross-linking revealed two binding components: a larger, 120 kDa species, and a smaller one with a molecular weight of 70 kDa. Interestingly, in human hematopoietic cells, granulocyte-macrophage colony-stimulating factor (GM-CSF) competes with IL-3 for binding to the IL-3 receptor. This cross-competition was not observed in the murine hematopoietic cells.

Structure of the IL-3 receptor

Molecular biology of the murine IL-3 receptor

Using an antibody (Aic2) that partially blocked IL-3 binding to murine cells, a cDNA termed AIC2A was cloned that encoded an 878 amino acid protein including a signal sequence. The mature protein is a glycoprotein of about 120 kDa. The AIC2A protein is a member of the type I cytokine receptor superfamily that includes the β and γ subunits of the IL-2 receptor, the receptors for IL-4 through IL-7, IL-9, GM-CSF, G-CSF, erythropoietin, leukemia inhibitory factor, oncostatin M, and ciliary neurotrophic factor. They have a common structural motif in their extracellular domains. This motif contains approximately 200 amino acids with fibronectin type III modules. Each module contains seven antiparallel β strands. There are four conserved cysteines in the N-terminal module and a unique tryptophan-serine-variable amino acid-tryptophan-serine (WSXWS) motif in the C-terminal module.

The AIC2A protein binds murine IL-3 with very

low affinity ($K_d = 10$ –20 nM). These binding characteristics are consistent with the low-affinity binding site on murine cells. A second cDNA was subsequently cloned that conferred high-affinity IL-3 binding in cooperation with AIC2A. The cDNA was termed SUT-1 and coded for a protein of 396 amino acids that is also a member of the type I cytokine receptor superfamily. The mature protein is about 70 kDa and binds IL-3 with a K_d of 40 nM. Coexpression of SUT-1 and AIC2A reconstitutes a receptor that binds murine IL-3 with a K_d of 300 pM. Thus, SUT-1 is now referred to as the α or ligand-binding subunit, and AIC2A as the β subunit of the murine IL-3 receptor. Further expression cloning using the Aic2 antibody led to the molecular cloning of a second AIC2 cDNA termed AIC2B. This cDNA encodes a protein of 896 amino acids with 91% homology to AIC2A, and its structure is basically the same as the IL-3 receptor β subunit; however, AIC2B binds neither IL-3 nor any other cytokine. Further studies have revealed that AIC2A is a subunit specific to the IL-3 receptor binding complex, and AIC2B is a β subunit shared with the GM-CSF receptor (Figure 1).

Molecular biology of the human IL-3 receptor

Using the AIC2A cDNA as a probe, the human homolog of the murine IL-3 receptor β subunit was cloned. The cDNA was termed KH97 and its overall structure was remarkably similar to the AIC2A/AIC2B proteins. It is about 56% homologous to the amino acid sequence of the murine AIC2 proteins. KH97 has two WSXWS motifs, but does not bind any IL-3 or other cytokines. Expression cloning using a cotransfection strategy with KH97 cDNA allowed the isolation of a cDNA that bound IL-3 with extremely low affinity. This cDNA, termed DUK-1, encodes a protein of 378 amino acids, and the extracellular domain contains a single WSXWS motif. The mature protein is about 70 kDa, and its structure is similar to the murine IL-3 receptor α subunit. The murine and human proteins however, show only about 70% homology at the amino acid level.

Transfection of COS-7 cells with the human IL-3 receptor α cDNA (DUK-1) yielded cells that bound IL-3 with very low affinity ($K_d = 100$ nM); however,

Figure 1 Structure of the murine and human IL-3 receptors and shared subunits. The murine system has two β subunits – AIC2A and AIC2B. AIC2A associates specifically with the α subunit of the IL-3 receptor, while AIC2B is shared by the IL-3/GM-CSF, and the IL-5 receptor α subunits. The human system possesses only one type of β subunit (β common or β_c), which forms high-affinity receptors with the α subunits of the IL-3/GM-CSF and IL-5 receptors.

cotransfection with KH97 reconstituted a high-affinity human receptor ($K_d = 100$ pM). Further studies of the GM-CSF receptor revealed that the GM-CSF and IL-3 ligand-binding subunits share the protein encoded by KH97 to form their respective high-affinity receptor complexes. Therefore the IL-3 receptor β subunit is termed β common or β_c , and the cross-competition between human IL-3 and GM-CSF is probably caused by competition for a limiting number of β_c by different ligand binding (α) subunits (Figure 2).

Signal transduction through the IL-3 receptor

Subunit requirements for signaling specificity and optimal cytokine response

Neither subunit of the IL-3R contains any known consensus sequences for intrinsic tyrosine kinase motifs or SH2/SH3 domains. Functional assays, however, have defined well-conserved domains in both the α and β_c subunits which are important for signal transduction. While dimerization of the β subunit appears to be essential for receptor activation, the α subunit is proposed to augment interactions of β_c with downstream signaling proteins. The ability of IL-3/GM-CSF/IL-5 to induce various effects depending on the target cells, may also be derived from the distinct cytoplasmic domains of their respective ligand-specific α subunits. Ligand-stimulated increases in tyrosine phosphorylation of the β_c subunit triggers IL-3-mediated signaling pathways. The observed lack of a correlation between cell pro-

liferation and β_c tyrosine phosphorylation has led some researchers to suggest that the IL-3R complex may contain additional components besides the α and β subunits.

Activation of non-receptor tyrosine kinases, serine/threonine kinases and recruitment of effector proteins into IL-3R-associated signaling complexes

Ligand stimulation of the IL-3 receptor rapidly induces tyrosine phosphorylation of effector proteins which subsequently trigger a cascade of intracellular responses. The activated receptor recruits nonreceptor tyrosine kinases and proteins containing SH2/SH3 structural motifs that participate in protein:protein interactions with β_c . Abrogation of IL-3 dependence in murine myeloid cells by retroviral tyrosine kinase oncogenes suggests that tyrosine phosphorylation events are critical to signaling pathways regulating cell proliferation and survival. Several members of the Src family of tyrosine kinases – p53/p56^{lyn}, p62^{yes} and p93^{fes} – have been implicated in IL-3R action. The β_c subunit appears to be constitutively complexed to p53/p56^{lyn}, phosphatidylinositol-3-kinase (PI3K) and JAK2. Engagement of the IL-3R leads to enhanced tyrosine phosphorylation and enzyme activity of JAK2 and PI3K, which are thought to play a role in signaling cell proliferation. Activation of JAK2, a non-Src type tyrosine kinase, is known to be necessary for IL-3-initiated mitogenesis and phosphorylation/nuclear translocation of the transcription factor STAT5 (signal transducer and activator of transcription). Stimulation with IL-3

Figure 2 Structural organization of the IL-3 receptor α and β subunits, both of which are members of the type I cytokine receptor family. The extracellular portion of the IL-3 receptor comprises a conserved motif (stippled boxes), which bears four conserved cysteine residues (CCCC) in the N-terminal side, and the sequence WSXWS in the C-terminal side. A short stretch of conserved amino acid sequence (RFLP) is found in the cytoplasmic domain of the α subunits as well. Box 1 and 2 motifs are part of a serine-rich region in the membrane-proximal domain, which is critical for IL-3-mediated cell proliferation.

also induces transient increases in the tyrosine phosphorylation status of the SH2-containing proteins Vav and p52^{shc}, and facilitates association of the latter with the docking protein GRB-2. These proteins are regulators of the interaction between IL-3R and the Ras pathway (Figure 3).

IL-3 stimulation of the serine/threonine kinases Raf-1 and members of the MAPK cascade serves to link tyrosine kinase-initiated signals to nuclear events involved in mitogenesis. *In vitro* experiments with glutathione-S-transferase/human IL-3R β c fusion proteins reveal that the membrane-proximal domain (amino acids 455–517) of the β c subunit is also capable of directly binding, and being phosphorylated by cytosolic serine/threonine kinases. Interestingly, the IL-3R activates a phosphatidylcholine-specific

phospholipase C, in conjunction with membrane translocation and activation of protein kinase C (PKC). IL-3R-activated PKC phosphorylates Raf-1 and the myristoylated alanine-rich C kinase substrate (MARCKS) protein. Phosphorylation of MARCKS is proposed to release the calmodulin bound to it, and lead to activation of calmodulin kinase. Calmodulin appears to be required for IL-3-induced DNA synthesis and primitive hematopoietic progenitor colony formation. Activation of PKC lies downstream of receptor-mediated increases in tyrosine phosphorylation, and seems to play a significant role in both IL-3R-regulated expression of the antiapoptotic gene *bcl-2*, and the suppression of apoptosis in factor-dependent cells.

Receptor subdomains mediating IL-3-dependent proliferative responses and suppression of apoptosis

Structure–function analyses using cytoplasmic domain deletion mutants of the β c subunit have revealed two regions which appear to transduce distinct signals, both of which are required for long-term survival and proliferation (Figure 4). The membrane-proximal region of the human β c subunit (amino acids 455–562), containing a Pro-X-Pro amino acid motif and an acidic residue-rich region, is required for activation of JAK2 tyrosine kinase and PI3K induction of the proto-oncogenes *pim-1*, *c-myc*, and mitogenesis. The amino acid sequence of the membrane-proximal region is highly conserved among β c, AIC2A and AIC2B (Figure 5). The membrane-distal region (amino acids 626–763) is essential for activation of Ras, Raf-1, MAPK and p70S6K and is related to induction of the *c-fos* and *c-jun* genes. A C-terminal-deleted β c, which lacks the membrane-distal cytoplasmic sequences required for activation of the Ras-Raf-1-MAPK cascade, induces DNA synthesis, but is incapable of supporting cell survival. Thus, despite a transient mitogenic response, cells expressing this mutant die by apoptosis in the presence of growth factor. Interestingly, the expression of a constitutively activated Ras protein appears to complement defective signaling through this mutant and restores the long-term proliferation response to cytokine stimulation. These data suggest that the IL-3R prevents apoptosis by stimulating a signaling pathway distinct from the induction of DNA synthesis.

Figure 3 A generalized schematic illustration of nonreceptor kinases, serine/threonine kinases, downstream effector molecules and target genes involved in IL-3 receptor signaling (proposed pathways indicated by dashed lines). The tyrosine kinases depicted seem to be capable of directly associating with human βc . Ligand stimulation leads to increases in βc tyrosine phosphorylation. activation of tyrosine kinases and PI3K, the latter catalyzes formation of the second messenger PI3,4,5- P_3 (phosphatidylinositol 3,4,5-triphosphate). PKC ζ is known to be activated by PI3,4,5- P_3 , suggestive of a role for this isotype of PKC in signaling through the IL-3 receptor. Evidence indicates that a 110 kDa serine-threonine kinase is also constitutively associated with the βc subunit. the substrates of this enzyme are not yet known. Serine/threonine phosphorylation of STATs is known to enhance their transactivation potential, the pathway/enzyme(s) that mediate this are unknown. IL-3 stimulates the tyrosine phosphorylation and complex formation between adapter proteins regulating activation of the Ras pathway (SHC, SOS-1, GRB-2). However, these events apparently do not promote the mass membrane translocation of the SH2 adapter protein complex. PY, phosphorylated tyrosine; DAG, diacylglycerol; Ser/ThrK, serine/threonine kinase.

Figure 4 Structure of the human IL-3 β c subunit: EC, extracellular domain; TM, transmembrane domain; gp130 homology domain, region containing the i) Pro-Asn-Pro motif that is important for tyrosine phosphorylation and cell proliferation, and ii) acid-rich domain containing 11 acidic and 1 basic amino acids which comprise a motif shared with the p75 signaling subunit of the IL-2 receptor. The membrane-proximal domain, extending between Arg456 and Asp544 is involved in mediating the proliferative signal through the IL-3 receptor. A region encompassing amino acids Val518 to Leu626 is responsible for major tyrosine phosphorylation, and the membrane-distal region (Leu626-Ser763) is required for activation of Ras, Raf-1, MAPK, and p70 S6K, as well as induction of *c-fos* and *c-jun*.

INTERLEUKIN 4

Stephen T Smiley and **Michael J Grusby**, Department of Cancer Biology, Harvard School of Public Health, Boston, Massachusetts, USA

The cytokine interleukin 4 (IL-4) is produced by several subsets of lymphoid cells and has pleiotropic actions on a variety of effector cells of the immune system (Table 1). Its major roles include promoting type 2 T helper (T_H2) cell differentiation, immunoglobulin E (IgE) secretion and eosinophil recruitment.

The human and murine IL-4 genes map to human chromosome 5 and mouse chromosome 11 and encode proteins that are comprised of 153 and 140 amino acid residues, respectively. Despite sharing 50% amino acid identity, human IL-4 is inactive on mouse cells and murine IL-4 is inactive on human cells. While natural IL-4 is an 18–20 kDa glycoprotein, recombinant IL-4 lacking glycosylation is fully active. As for most secreted polypeptides, IL-4 contains an N-terminal signal sequence that is post-translationally cleaved.

IL-4 is produced by several subsets of activated lymphoid cells. T_H2 cells are particularly important sources of this cytokine, as they are critical for initiating humoral immunity against extracellular pathogens. In addition to secreting IL-4, T_H2 cells also require IL-4 for their own development. It has been suggested that specialized T cells that express natural killer (NK) cell markers and secrete large amounts of IL-4 immediately after T cell receptor stimulation produce the IL-4 that promotes T_H2 cell differentiation. However, T_H2 cell differentiation can proceed normally in strains of genetically altered mice that lack these NK-like T cells. Activated mast cells, basophils and γ/δ T cells can also produce IL-4 and thus may be other sources of the IL-4 that is required for T_H2 cell differentiation.

Secretion of IL-4 is transcriptionally regulated and, as such, the IL-4 promoter has been extensively studied. Functionally important binding sites for AP-1 and NF-AT transcription factors are present in the IL-4 promoter. However, AP-1 and NF-AT also bind to the promoters of other cytokine genes expressed independently of IL-4, suggesting that cell-specific expression of IL-4 is dictated by additional factors. Indeed, recent studies indicate that activity of the proto-oncogene *c-maf* may be responsible for the specific transcription of the IL-4 gene in T_H2 cells.

As is the case with other cytokines, IL-4 elicits biological responses by interacting with a specific cell surface receptor. The IL-4 receptor is expressed on a wide variety of cell types including T and B lymphocytes, macrophages, fibroblasts, keratinocytes and endothelial cells. The receptor is composed of at least two chains: a 140 kDa ligand-specific α chain and a 75 kDa γ_c chain. The α chain is also a component of the IL-13 receptor, while the γ_c chain is shared by several other cytokine receptors, including those for IL-2, IL-7, IL-9 and IL-15.

Table 1 Pleiotropic functions of IL-4

- Acts as a costimulant for growth in B cells, T cells and mast cells.
- Increases the survival of cultured B cells, T cells and other hematopoietic cell types
- Induces the expression of MHC class II on B cells and monocytes and CD23 on B cells
- Directs immunoglobulin class switching to the IgG1 and IgE isotypes
- Directs T helper cell differentiation to the T_H2 type
- Diminishes the inflammatory functions of monocytes and macrophages while enhancing their antigen presenting functions
- Can inhibit the growth of transplanted tumors *in vivo* and can diminish the growth of certain cancer cells *in vitro*
- Induces growth and chemotaxis in human fibroblasts and the production of IL-6, extracellular matrix proteins and ICAM-1
- Regulates expression of VCAM-1 on human endothelial cells and VLA-4 on T cells and eosinophils
- Reduces Cl^- secretion by intestinal epithelial cells

Activities of IL-4

IL-4 was first identified as a helper T cell product with the capacity to costimulate B cell growth *in vitro*. Early studies also revealed that IL-4 augments expression of major histocompatibility complex (MHC) class II and Fcε receptor molecules on murine B cells and promotes their secretion of IgE and IgG1. Consequently, IL-4 was initially named B cell stimulatory factor. Both transgenic IL-4-overexpressing and IL-4-deficient mice have been generated. *In vivo*, transgenic overexpression of IL-4 dramatically increases basal levels of serum IgE, and IL-4-deficient mice fail to produce antibodies of the IgE-isotype and produce diminished amounts of IgG1. Thus, IL-4 is essential for B cell secretion of IgE and augments production of IgG1 *in vivo*.

In addition to regulating B cell growth and immunoglobulin secretion, IL-4 also affects T cells. *In vitro*, IL-4 promotes T cell growth and can potently induce cytolytic T cell activity. IL-4 also induces the differentiation of naive CD4⁺ T cells into T_H2 cells, which are characterized by their capacity to secrete the cytokines IL-4, IL-5 and IL-10 upon activation, while simultaneously inhibiting the generation of T_H1 cells, which secrete IL-2 and interferon γ (IFNγ). Indeed, *in vivo* the development of T_H2 cells is critically dependent upon IL-4, as it is completely abrogated in transgenic IL-4 deficient mice. Accordingly, IL-4-deficient mice are hypersensitive to infections that are normally eradicated by T_H2 cells, such as the nematode *Nippostrongylus brasiliensis*.

IL-4 may also influence T cell maturation in the thymus. A burst of IL-4 expression occurs at day 15 of gestation in the fetal thymus of normal mice, suggesting that thymic IL-4 expression plays a role in normal T cell development. *In vitro*, IL-4 affects thymocyte maturation, as CD8⁺ T cells selectively develop from IL-4-treated thymocyte cultures. Likewise, the total number of immature thymocytes is reduced, while the number of mature CD8⁺ thymocytes is increased when IL-4 is overexpressed *in vivo*. However, all thymocyte subsets develop normally in IL-4-deficient mice. Thus, *in vivo* IL-4 expression is not critical for T cell maturation in the thymus.

In vivo, IL-4 regulates eosinophil recruitment. Transgenic mice with T cells overexpressing IL-4 develop an ocular inflammatory lesion characterized by a striking number of eosinophils and mast cells. IL-4-mediated eosinophilia is also observed when nonimmunogenic tumor cells are transfected with an IL-4 cDNA and implanted into mice. The IL-4-expressing tumor cells become immunogenic, and their clearance is associated with an infiltrate of tumoricidal eosinophils. The IL-4-promoted eosino-

philia has been shown to be dependent upon IL-5. Thus, the depressed eosinophil responses in IL-4-deficient mice are probably a consequence of their failure to generate IL-5-producing T_H2 cells.

Molecular mechanisms of IL-4 activity

At least two distinct IL-4 receptor-associated signaling pathways are activated when IL-4 binds to the membrane-bound form of its receptor. One pathway leads to the phosphorylation of an insulin receptor substrate (IRS), named IRS-2. Phosphorylated IRS-2 then associates with phosphatidylinositol 3-kinase. A mutant cell line that cannot phosphorylate IRS-2 exhibits diminished growth in response to IL-4, suggesting that the IRS-2 pathway may regulate IL-4-associated proliferative responses.

The second pathway activated by binding of IL-4 to its receptor is initiated by the Janus kinase family members, JAK1 and JAK3. These JAKs are constitutively associated with the IL-4 receptor and are activated by phosphorylation when IL-4 binds to the receptor. Once activated, the JAKs phosphorylate a member of the signal transducing and activation of transcription (STAT) family, STAT6. This protein exists in a latent form in the cytoplasm and it dimerizes and migrates to the nucleus when activated by phosphorylation. There it promotes the transcription of genes containing promoters with STAT6 binding sites. Lymphocytes from transgenic STAT6-deficient mice do not differentiate into T_H2 cells in the presence of IL-4. In addition, IL-4-induced increases in B cell expression of MHC class II antigens are abrogated in the absence of STAT6, as are IL-4-induced B and T cell proliferative responses. Thus, STAT6 appears to mediate most responses to IL-4, including T_H2 cell differentiation.

As the transcription factor STAT6 is a critical component of signaling through the IL-4 receptor, the expression of a specific set of genes presumably mediates many of the biologic effects of IL-4. As mentioned, IL-4 is critical for B cell class switching to IgE and promotes the switching of murine cells to IgG1. Class switching is initiated by IL-4-induced transcription of immunoglobulin genes, and functional STAT6 binding sites have been identified in the promoters of the IgE and IgG1 genes. In addition, B cell expression of MHC class II antigens, CD23, CD40, Thy-1 and receptors for IL-4 and Fcε are each augmented by exposure to IL-4. Thus, transcription of STAT6-dependent genes can account for many of the activities of IL-4 on B cells.

In contrast, the mechanisms by which IL-4 regulates T cells are less well understood. IL-4 and IL-12 exert antagonizing effects on T cell differentiation.

While IL-4 promotes the differentiation of naive T cells into T_H2 cells, IL-12 promotes their differentiation into T_H1 cells. When both cytokines are present, IL-4 dominates and T_H2 cells develop. In part, this is because IL-4-exposure causes a downregulation of the β chain of the IL-12 receptor, thus abrogating signaling via IL-12 receptors. Thus, the production of IL-4 during early phases of an immune response will critically affect the types of effector cells that develop.

However, the mechanism by which IL-4 directly promotes the generation of T_H2 cells is currently unknown. Few IL-4-regulated T cell genes have been identified. The proto-oncogene *c-maf* is a potent inducer of IL-4 transcription, and *c-maf* is expressed in differentiated T_H2 cells, but not in T_H1 cells. Thus, if IL-4 induces *c-maf* expression, *c-maf* could in turn promote IL-4 expression and perhaps induce stable T_H2 cell differentiation. However, it has not yet been demonstrated that either IL-4 or STAT6 directly promote *c-maf* expression. Thus, despite its critical requirement for T_H2 cell differentiation *in vivo*, the mechanisms by which IL-4 promotes the development of T_H2 cells from naive precursors remain to be elucidated.

INTERLEUKIN 4 RECEPTOR

Achsah D Keegan, Department of Immunology, Jerome H Holland Laboratory, American Red Cross, Rockville, Maryland, USA

Interleukin-4 (IL-4) is a cytokine, produced by T cells, mast cells and basophils, that elicits a diverse array of biological responses. These functions range from the regulation of helper T cell phenotype and the production of immunoglobulin E (IgE) by B lymphocytes to the regulation of the adhesive properties of endothelial cells via VCAM-1 and the regulation of ion secretion by intestinal epithelial cells. In keeping with this diverse array of biological effects, high-affinity binding sites for IL-4 (K_d 20–300 pM) have

been detected on a variety of hematopoietic and non-hematopoietic cell types at levels ranging from 100 to 5000 sites per cell.

Cell surface IL-4 receptor complex

The structure of the IL-4 receptor complex was initially characterized using chemical cross-linking of [¹²⁵I]IL-4 to molecules on the surface of IL-4-responsive cells. These early studies found two major com-

plexes. One complex contained [^{125}I]IL-4 bound to a protein of ~140 kDa. The second complex often contained 80 and 70 kDa molecules cross-linked to [^{125}I]IL-4. These molecules have since been cloned and sequenced.

The molecular cloning of cDNA encoding IL-4 binding and its expression in COS-7 cells indicated that a single chain of ~140 kDa constituted a high-affinity IL-4 binding site (IL-4R α). The IL-4R α bears the characteristic pairs of cysteine residues and the WSXWS motif found in other members of the hematopoietin receptor superfamily, a classic transmembrane domain, and one of the largest cytoplasmic domains of this family with over 500 amino acids. During the cloning process, a second naturally occurring form of mRNA was observed in murine cells. This form gave rise to a soluble high-affinity IL-4-binding protein of 40 kDa. The nucleotide sequence of the cDNA encoding these molecules indicated that both shared the extracellular, ligand-binding domain, but that the 40 kDa form lacked the transmembrane and cytoplasmic domains. Examination of the structure of the murine gene (Figure 1) revealed an exon (exon 8) that specified a soluble version of the IL-4 receptor. Thus the two species of receptors are likely to arise from alternative splicing.

The IL-4 receptor complex also contains other polypeptide chains, consistent with the early cross-linking studies. The γ chain of the IL-2 receptor (common γ or γc) associates with the IL-4R α chain following the binding of IL-4. This complex has been called the type I IL-4 receptor (Figure 2). In addition, the low-affinity binding chain for IL-13 (IL-13R α), a cytokine that elicits biological responses similar to IL-4, can also function as an IL-4R α -associating chain. The IL-4 receptor containing the IL-13R α has been termed type II. Interestingly, a chimeric receptor consisting of the extracellular domain of the erythropoietin receptor and the cytoplasmic domain of the IL-4R α is competent to signal cellular proliferation, suggesting that association of two IL-4R α chains is sufficient to induce signaling. However, it is not yet

Figure 1 Exon structure of the gene encoding the murine IL-4R α . Exons 1–12 are depicted. Introns are not to scale. The two pairs of cysteine residues (CC) and the WSXWS motif are shown in the appropriate location. Exon 8 codes for the carboxy-terminus of the soluble form of the receptor. In the cell surface form, exon 8 is spliced out leaving exons 7 and 9 adjoining.

Figure 2 Models of IL-4 receptor complexes. Models of the IL-4 receptor complexes best supported by experimental data are shown. The type I receptor consists of the IL-4R α and the γc . JAK1 binds the IL-4R α and JAK3 binds the γc . The type II IL-4 receptor consists of the IL-4R α and the low-affinity IL-13 binding chain called IL-13R α .

clear whether this type of IL-4 receptor is functional *in vivo*.

Signal transduction by the IL-4 receptor complex

Treatment of cells with IL-4 activates several signaling pathways that involve the activation of cytoplasmic tyrosine kinases (Figure 3). The Janus family of tyrosine kinases (JAKs) are of critical importance in initiating these pathways. JAK1 is associated with IL-4R α , while JAK3 is coupled to the γc . The identity of the kinase(s) associated with IL-13R α is not yet clear, but it is not JAK3. Heterodimerization of the receptor subunits is thought to activate the kinases.

One of the signaling pathways initiated by IL-4 includes the activation of a latent, cytoplasmic transcription factor that is a member of the signal transducers and activators of transcription (STAT) family, termed STAT6. The JAK-dependent tyrosine phosphorylation of STAT6 results in its dimerization and translocation to the nucleus. By virtue of its ability to bind to DNA sequences found in the promoter elements of IL-4 responsive genes, STAT6 participates in the IL-4-induced regulation of gene expression.

A second signaling pathway activated via the IL-4 receptor involves the insulin receptor substrate (IRS) family (IRS-1 and IRS-2). Tyrosine phosphorylated sites within IRS-1 and IRS-2 associate with high

Figure 3 Signaling pathways emerging from the IL-4 receptor complex. The binding of IL-4 to the IL-4R α induces its association with γ c (or with the IL-13R α). The Janus family tyrosine kinases JAK1 and JAK3 bind to the IL-4R α and the γ c cytoplasmic domains, respectively, and become activated when they are brought in close proximity. Activation of the kinases leads to the tyrosine phosphorylation of the IL-4R α and several signaling molecules including STAT6, IRS and Shc. The phosphorylation of STAT6 results in its dimerization and translocation to the nucleus where it can bind to promoter elements and regulate gene expression. The phosphorylation of IRS results in its association with and activation of other signaling molecules. IRS has been shown to be important in regulating cell survival and entry into cell cycle in response to IL-4. The function of phosphorylated Shc is unclear.

affinity to cellular proteins that contain SH2 domains, including the p85 subunit of phosphatidylinositol 3-kinase (PI3K), growth factor receptor-bound protein 2 (GRB2), the SH2 and SH3 domain containing adaptor protein nck, the src-family kinase fyn, and the src-homology protein tyrosine phosphatase 2. This pathway contributes to the IL-4-induced protection from cell death and entry into cell cycle.

The importance of the transforming protein Shc in IL-4 signaling is not yet known. However, IL-4 clearly induces the tyrosine phosphorylation of Shc in several cell types. The precise roles of the STAT6, IRS and Shc pathways (Figure 3) in regulating biological responses transmitted by the IL-4 receptor will require further detailed analyses.

Interleukin 5 (IL-5) controls the production of eosinophils. It has remarkable biological specificity *in vivo*. Overexpression leads to eosinophilia, and gene ablation or treatment with anti-IL-5 antibody abolishes eosinophilia. While IL-5 has activity on B cells in the mouse *in vitro*, the biological role of this activity remains doubtful. Furthermore, human IL-5 has little if any activity on human B cells *in vitro*.

Production of eosinophils *in vivo*

Transgenic mice overproducing IL-5 showed high-level eosinophil production which was proportional to the transgene copy number. These animals have detectable levels of IL-5 in the serum, and show a profound and lifelong eosinophilia, with large numbers of eosinophils in the blood, spleen, bone marrow, lung and gut wall. Interestingly, despite the massive long-lasting eosinophilia, the mice remained apparently normal. This illustrates that increased numbers of eosinophils are not themselves harmful. The tissue damage seen in allergic reactions and other diseases must be due to other factors.

Mice infected with *Nippostrongylus brasiliensis* develop eosinophilia and increased levels of immunoglobulin E (IgE). However, when treated with anti-IL-5 antibody, no eosinophils were observed and the number of eosinophil precursors present in the bone marrow was also depressed. As the anti-IL-5 antibody does not block the effect of IL-3 or granulocyte-macrophage colony-stimulating factor (GM-CSF), these experiments demonstrate the essential role that IL-5 performs in the control of eosinophilia in such parasite infections. In addition they show that the apparent redundancy seen *in vitro*, where both IL-3 and GM-CSF are also able to induce eosinophil production, does not operate in these infections.

Targeted disruption of the IL-5 gene by homologous recombination results in animals which do not develop eosinophilia when infected with *Mesocostoides corti*. Normal mice infected with *N. brasiliensis* exhibit peripheral eosinophilia, eosinophilic infiltration of the lung and lung damage. The IL-5-deficient mice show no peripheral eosinophilia, a 10-fold decrease in lung cellularity and no lung damage. There was no effect on baseline levels of immunoglobulin isotypes in these mice. These experiments confirm the link between IL-5 and eosinophilia.

To examine the role of eosinophils in lung dam-

age, IL-5-deficient and normal mice were sensitized to ovalbumin and then exposed to ovalbumin aerosol. Normal mice developed massive lung eosinophilia accompanied by considerable lung damage, the IL-5-deficient mice however, showed no increase in eosinophils and no lung damage. When these mice were infected with recombinant vaccinia virus engineered to express IL-5, the eosinophilic infiltration and lung damage was completely restored. In contrast when the same experiment was carried out with mice in which the IL-4 gene had been disrupted and which did not produce IgE, aeroallergen-induced recruitment of eosinophils and lung damage was similar to that seen in the normal mice.

Structure

In its native form IL-5 is a heterogeneous glycoprotein of mean M_r of 45 kDa. The cDNA encodes a protein of 135 residues which includes a leader sequence of 20 residues. Thus the mature polypeptide consists of 115 residues with a calculated mass of 12 000. The active molecule is a homodimer of calculated mass 24 000, indicating that the native molecule is heavily glycosylated. Human IL-5 has N-linked carbohydrate at position Asn28, and O-linked at Thr3, and murine IL-5 is glycosylated at analogous sites, with an additional N-linked oligosaccharide at Asn55. A possible N-linked site at Asn71 is not glycosylated in either species.

The two polypeptide chains form helical bundles each containing three helices (A-C) from one chain and one from the other (D'). The dimeric protein is held together by two disulfide bridges between residues 42 and 84 of opposing chains. Mutation of one of the cysteines prevents dimerization and the resulting monomer is inactive, probably because it is unstable.

Contact points between IL-5 and its receptor chains have been investigated by mutation analysis, constructing species hybrid molecules and the mapping of neutralizing antibodies. These studies indicate that residues in the D helix, Asn108 and Glu110 and in loop 3 (between the C and D helices), Lys84 and Arg91, are important for binding to the receptor α chain. The receptor β chain interacts with Glu13 (of helix A). Despite the dimeric nature of IL-5 suggesting two potential receptor binding sites, only one α chain binds to IL-5, although the number of β chains in the complex is not known.

Gene structure and expression

In humans, the IL-5 gene is located on chromosome 5q31 in a cluster with IL-13, IL-4, IL-3 and GM-CSF. The coding sequence of the IL-5 gene forms four exons. The 5' flanking region of the IL-5 RNA initiation site contains several motifs involved in the transcription of the gene. There is a short sequence named the conserved lymphoid element 0 (CLE0), just upstream of the TATA box. This element is essential for promoter activity. It binds factors of the AP-1 family (*c-fos* and *junB*) together with NF-AT regulatory proteins and has been shown to mediate the response to T cell activation signals generated by phorbol myristate acetate (PMA) in combination with either anti-CD28 or cAMP. The participation of OCT factors and GATA4 proteins at two sites immediately upstream of the CLE0 element are also critical for the regulation of the gene. Two related palindromic elements which resemble the NF- κ B consensus sequence, have been identified. These have counterparts in the mouse gene and appear to be specific for IL-5. Electrophoretic mobility shift assay (EMSA) suggests that similar proteins bind to both elements and an interaction between the elements has an important regulatory effect.

A series of positive and negative regulatory elements involved in the induction of the mIL-5 gene has been identified using the mouse T cell clone D10.G4.1. A sequence located between positions -130 and -176 contains at least two protein-binding sites which participate in the activation of the IL-5 promoter and two negatively acting elements were mapped between positions -261 and -300 and positions -392 and -431. A novel repressor element (mDRE1) consisting of four repeats of an 8 nucleotide element have been identified in the 3' region of the mouse gene. This is active in both the EL4 lymphoma cell line and primary mouse T cells. No obvious human counterpart has yet been identified.

IL-5 has a remarkable translational regulatory mechanism identified by a deletion in the 3' region of the RNA. This deletion results in a 10-fold increase in expression in monkey COS cells and in reticulocyte lysates. Both this region and nucleotides forming a loop structure in the 5' region are necessary for the downregulation of translation. The proteins binding to the RNA are present in reticulocytes, COS cells as well as T cells, and so this may be a general control mechanism in the regulation of many proteins.

IL-5 receptor complex

The receptor complex consists of an α chain and a β_c chain. Both chains have structures characteristic of the hematopoietin receptor superfamily. The α chain is a glycoprotein of 415 amino acids and binds with low affinity to IL-5. The β chain itself does not bind to IL-5, but associates with the α chain to generate the high-affinity receptor. The β chain is common to the receptors for IL-3 and GM-CSF.

Because of the difficulty in obtaining sufficient numbers of eosinophils, progress in characterizing the eosinophil IL-5R has been slow. Murine eosinophils have been calculated to express approximately 50 high-affinity receptors (K_d in the range $4-6 \times 10^{-11}$ M), and approximately 5000 low-affinity receptors (K_d in the range $0.3-2.0 \times 10^{-9}$ M). Initial work on the human receptor used a clone of the human promyelocytic leukemia cell line HL-60.

These cells express only a single population of high-affinity IL-5-binding sites and cross-linking studies show IL-5 associating with two membrane proteins of M_r 60 000 and 13 000. Similarly, only a single high-affinity receptor population has been identified on human eosinophils. This was found to be a high-affinity receptor in the range K_d 170-330 pM ($3-6 \times 10^{-11}$ M).

Human eosinophils express three different transcripts from the same IL-5R α locus. In addition to the membrane-anchored receptor, two soluble isoforms can be produced. Intriguingly, one of these soluble variants is the predominant (>90%) transcript detected in mature, circulating eosinophils or in eosinophils obtained from cord blood cultures. This major soluble isoform arises from splicing to a soluble-specific exon, which precedes the exons encoding the transmembrane anchor.

INTERLEUKIN 6

Tadashi Matsuda, Department of Biochemistry, St Jude Children's Research Hospital, Memphis, Tennessee, USA

Tadamitsu Kishimoto, Department of Medicine III, Osaka University Medical School, 2-2 Yamada-oka, Suita-City, Osaka, Japan

Interleukin 6 (IL-6) is a multifunctional cytokine produced by various cells. The molecular cloning of the cDNAs encoding B cell stimulatory factor 2 (BSF-2), interferon β 2, and 26 kDa protein showed that all these molecules are identical. Furthermore, hybridoma/plasmacytoma growth factor (HPGF) and hepatocyte-stimulating factor (HSF) were also found to be identical to this molecule and, therefore, this molecule has been called IL-6. Subsequent studies demonstrated that IL-6 acts not only on B cells but also on hematopoietic stem cells and hepatocytes and induces hematopoiesis as well as acute phase reactions. As summarized in **Figure 1**, it was also shown to act on T cells, nerve cells, keratinocytes, renal mesangial cells, megakaryocytes and myeloma/plasmacytoma cells. Since antibody production, hematopoiesis, and acute phase reactions are three major responses against infection, inflammation and tissue injury, IL-6 may have a central role in host defense mechanisms. On the other hand, the deregulation of IL-6 gene expression was shown to be involved in the pathogenesis of polyclonal and monoclonal B cell abnormalities, such as rheumatoid arthritis and multiple myeloma.

Structure of IL-6

The characterization of the IL-6 molecule is summarized in **Table 1**. Only granulocyte colony-stimulating factor (G-CSF) showed a significant homology with IL-6, especially as the position of four cysteine residues of both proteins matches completely. However, these cysteine residues have no effect on the biological activities of IL-6. Furthermore, the organization of the IL-6 gene shows a distinct similarity with G-CSF. Both genes have the same number of exons and introns and their exon sizes are strikingly similar. Taken together, these findings suggest that both genes might be derived from a common ancestor gene.

Functions of IL-6

Immune response

Interleukin 6 was originally identified as a T cell-derived lymphokine that induces final maturation of B cells into antibody-producing cells. Recombinant human IL-6 acts on B cells activated with *Staphylococcus aureus* Cowan I or pokeweed mitogen (PWM) to induce immunoglobulin M (IgM), IgG and IgA production, but not on resting B cells. Anti-IL-6 antibody was found to inhibit PWM-induced Ig production, indicating that IL-6 is one of the essential factors in PWM-induced Ig production. Furthermore, IL-6 was shown to augment the primary and secondary anti-SRBC (sheep red blood cell) antibody production in mice *in vivo*. Also IL-6 could enhance IgA synthesis in murine Peyer's patch B cells which were already committed to IgA production. Murine IL-6 was also shown to act on murine B cells activated with anti-Ig or dextran sulfate; IL-6 and IL-1 synergistically stimulate the growth and differentiation of these murine B cells. Interleukin 6 could also induce the growth and differentiation of T cells and promoted the growth of mitogen-stimulated thymocytes and peripheral T cells. It was also shown to induce the differentiation of cytotoxic T cells in the

presence of IL-2 from murine as well as human thymocytes and splenic T cells.

Hematopoiesis

By shortening the G_0 period of the stem cells, IL-6 and IL-3 synergistically induce the colony formation of multipotent hematopoietic progenitors. This synergic effect of IL-3 and IL-6 was also observed in serum-free culture conditions, suggesting that IL-6 may enhance the sensitivity of multipotent stem cells to IL-3. When bone marrow cells were transplanted to lethally irradiated recipients, the survival rate at day 30 was only 20%. However, when these cells were precultured with IL-6 and IL-3 before transplantation, the survival rate was raised to 90%.

Furthermore, IL-6 induced the maturation of megakaryocytes *in vitro* and *in vivo*. IL-6 promoted marked increments in size and acetylcholinesterase activity, a marker enzyme of this lineage. IL-6 also induced a significant shift toward higher ploidy classes.

Acute phase response

The acute phase response is a systemic reaction against inflammation, infection, or tissue injury, which is characterized by leukocytosis, fever, increased vascular permeability, alteration in plasma metal and steroid concentration, along with increased levels of acute phase proteins. The production of acute phase proteins by hepatocytes is regulated by several soluble factors, such as IL-1, tumor necrosis factor (TNF) and HSF. Among these factors, only HSF could induce the full acute phase proteins. It was demonstrated that recombinant IL-6 can function as HSF. It can induce various acute phase proteins, such as fibrinogen, α_1 -antichymotrypsin, α_1 -acid glycoprotein, and haptoglobin, in a human hepatoma cell line. In addition, IL-6 induces serum amyloid A, C reactive protein, and α_1 -antitrypsin in human primary hepatocytes. In the rat, IL-6 induces fibrinogen, cysteine proteinase inhibitor, and α_2 -macroglobulin. Serum albumin was negatively regulated by IL-6.

Nerve system

Interleukin 6 mRNA was induced by IL-1-stimulated glioblastoma cells or astrocytoma cells, suggesting that IL-6 may have certain effects on neural cells. The rat pheochromocytoma cell line PC12 is a typical neural differentiation model. Nerve growth factor (NGF) induces chemical, ultrastructural, and morphological changes in the PC12 cell. Also IL-6 was found to induce the typical differentiation of this cell into neural cells and found to be produced by virus-infected microglial cells and astrocytes. It also induced the secretion of NGF by astrocytes. In CNS IL-6 production may be involved in repair mechanisms in the course of viral infection.

IL-6 and disease

The involvement of IL-6 in disease was first suggested in cardiac myxoma. The patients frequently show symptoms related to polyclonal plasmacytosis, such as hypergammaglobulinemia and the presence of various autoantibodies and an increase in acute phase proteins. These symptoms disappear upon the resection of the tumor, suggesting that myxoma-derived factors may induce these phenomena. It was found that myxoma cells express a large amount of IL-6. Abnormal IL-6 production was also observed in patients with Castleman's disease. In these patients, activated B cells in the germinal centers of hyperplastic lymph nodes were found to produce IL-6. After the resection of these lymph nodes, clinical improvement and a decrease in serum IL-6 levels were observed. This evidence suggests that deregulated IL-6 production may induce polyclonal B cell activation and increases in acute phase proteins. This possibility was also suggested in rheumatoid arthritis (RA). High levels of IL-6 were detected in synovial fluid from the joints of patients with active RA. Interleukin 6 is a potent growth factor for murine hybridomas/plasmacytomas, suggesting a possible involvement of IL-6 in the generation of plasmacytomas/myelomas. Furthermore, a study with human myeloma cells isolated from patients with multiple myelomas demonstrated that IL-6 is an autocrine growth factor for human myeloma cells. All the evidence suggests that deregulated gene expression of IL-6 may be involved in the polyclonal B cell activation and generation of plasma cell neoplasia.

Mesangial proliferative glomerulonephritis (PGN) is histologically characterized by proliferation of mesangial cells (MC), suggesting the involvement of the growth factor for MC in the pathogenesis of this disease. It was shown that IL-6 is an autocrine growth factor for MC. It could be detected in urine

Table 2 Diseases related to deregulated expression of IL-6

<i>Polyclonal B cell activation or autoimmune diseases</i>
Cardiac myxoma
Rheumatoid arthritis
Castleman's disease
AIDS
Uterine cervical carcinoma
Alcoholic liver cirrhosis
<i>Neoplasias</i>
Plasmacytoma and myeloma
Lennert's T cell lymphoma
Renal cell carcinoma
<i>Others</i>
Mesangial proliferative glomerulonephritis

samples from patients with PGN. Furthermore, a close relationship was observed between the level of urine IL-6 and the progression of PGN. These results suggest that deregulated IL-6 production in MC is involved in the pathogenesis of PGN. Other diseases related to the deregulated expression of IL-6 are summarized in Table 2.

IL-6 transgenic mice

Transgenic mice with the human IL-6 gene conjugated with the immunoglobulin enhancer have been produced. The E μ -IL-6 gene was expected to express IL-6 constitutively in B lineage cells. In all founder mice, a marked increase in serum IgG1 and enlargement of spleen, thymus and lymph nodes were observed. All of the mice died within several months and the histology of lymph nodes showed a massive infiltration of plasma cells. However, Southern blot analysis of DNAs from lymph nodes or spleen did not show any monoclonal or oligoclonal rearrangements of the Ig heavy chain genes. Furthermore, plasma cells were not transplantable to syngeneic recipients. The other changes consistently observed in E μ -IL-6 transgenic mice were an increase in mature megakaryocytes in bone marrow and mesangial proliferative glomerulonephritis.

In IL-6 knockout mice approximately 80–90% reductions of antiviral antibody response and acute phase reaction have been observed, confirming that IL-6 is one of the essential factors for antibody production and the acute phase reaction.

INTERLEUKIN 6 RECEPTOR

Tadamitsu Kishimoto, Department of Medicine III, Osaka University Medical School, 2-2 Yamada-oka, Suita-City, Osaka, Japan

The specific receptor for interleukin 6 (IL-6) was found to be expressed on lymphoid as well as non-lymphoid cells in accordance with the multifunctional properties of IL-6. Among human cell lines, IL-6 receptor is expressed on Epstein-Barr virus-transformed B cell lines (CESS, SKW-CL4), a histiocytic leukemia cell line (U937), a promyelocytic leukemia cell line (HL-60), myeloma cell lines (U266, ARH77), hepatoma cell lines (HepG2, Hep3B), and a glioblastoma cell line (SK-MG-4). In normal tissues, IL-6 receptor is expressed on hepatocytes and monocytes, not on resting B cells but on activated large B cells with IgD negative phenotype, and on CD4⁺/CD8[−] as well as CD4[−]/CD8⁺ T cells (in the case of T cells, no significant change after phytohemagglutinin (PHA) stimulation). The number of receptors on each cell is relatively small; i.e. 100–20 000. Scatchard plot analysis demonstrated the presence of high- and low-affinity IL-6 binding sites – $K_d = 10^{-11}$ M and 10^{-9} M respectively. The number of high-affinity sites is usually 5–10% of the total binding sites.

Complementary DNA encoding human IL-6 receptor capable of expressing both high- and low-affinity binding sites has been cloned. Human IL-6 receptor consists of 468 amino acids (a.a.), ~19 a.a. signal peptide, ~339 a.a. extracellular portion, ~28 a.a. transmembrane domain, ~82 a.a. intracytoplasmic portion. There are six potential N-linked glycosylation sites (Asn-X-Ser/Thr) and 11 cysteine residues. The mature receptor has O- and N-glycosylation and its molecular weight is about 80 kDa.

Inspection of the IL-6 receptor sequence shows that the region between position ~20 and ~110 fulfills the criteria for the constant 2 (C2) set of the immunoglobulin (Ig) superfamily. The extracellular

region following the C2 set domain has homology with the extracellular portion of IL-2 receptor β chain, IL-3 receptor, IL-4 receptor, IL-7 receptor, growth hormone receptor, and erythropoietin receptor (a cytokine receptor family having four cysteines and the motif Trp-Ser-X-Trp-Ser). The intracytoplasmic portion of IL-6 receptor is short and has no tyrosine kinase domain, unlike certain other growth factor receptors, and shows no homology with other known functional proteins. Thus it indicates that transduction of the IL-6 signal could be mediated through another molecule associated with the IL-6 receptor.

The mouse IL-6 receptor has 460 amino acid residues and has homology to the human receptor over its whole sequence.

When the IL-6 receptor was precipitated with monoclonal anti-IL-6 receptor antibody under mild lysis (1% digitonin), only the 80 kDa IL-6 receptor molecule was observed. Another polypeptide chain of 130 kDa was coprecipitated with IL-6 receptor, when the cells were incubated with IL-6 at 37°C for 30 min before digitonin lysis. This observation suggested that IL-6 triggered the association of the 80 kDa IL-6 receptor with a 130 kDa molecule. This 130 kDa molecule was a membrane-anchored glycoprotein (gp130), since it was labeled when labeling the cell surface and its molecular weight was decreased by glycanase treatment.

The murine gp130 homolog could be associated with the human IL-6 receptor by IL-6 stimulation, using a mouse transfectant with human IL-6 receptor cDNA. gp130 alone cannot bind IL-6 if the parental cell line has no IL-6-binding sites.

The murine myeloid cell line M1 transfected with either normal human IL-6 receptor cDNA or deletion

mutant IL-6 receptor cDNA lacking the intracytoplasmic portion was growth inhibited and induced to differentiate to macrophages by IL-6 stimulation. This result indicates that the intracytoplasmic portion of IL-6 receptor is not required for the signal transduction.

Soluble IL-6 receptor lacking the transmembrane and cytoplasmic domains could associate with gp130 in the presence of IL-6 and provide the IL-6 signal.

These results show that the IL-6 receptor system is composed of two functional chains, the ligand-binding 80 kDa IL-6 receptor and the nonligand binding gp130. Interleukin 6 triggers the association of IL-6 receptor and gp130 on the cell membrane and gp130 provides the IL-6 signal. gp130 functions as a signal transducer not only for IL-6 but also for various cytokines belonging to the IL-6 family, such as LIF, CNTF, oncostatin M, IL-11 and cardiotrophin. Homodimerization of gp130 or heterodimerization of gp130 and LIF receptor activates the JAK-STAT3 signaling pathway.

INTERLEUKIN 7 AND ITS RECEPTOR

Shin-Ichi Nishikawa, Department of Molecular Genetics, Faculty of Medicine, Kyoto University, Kyoto, Japan

Millions of lymphocytes are produced each day and recruited to the periphery. In human and mouse, the major sites of their production are bone marrow and thymus for B and T lymphocytes, respectively. Although *in vitro* propagation of T cell progenitors and human B cell progenitors is yet to be attained, it has been possible to maintain the growth of murine B cell progenitors in culture since Whitlock and Witte developed culture conditions modified from those of Dexter's long-term bone marrow culture. Whitlock–Witte type long-term culture consists of two components: a hematopoietic cell lineage including B cell progenitors and adherent stromal cells which support their growth. Cloned stromal cell lines were established which were able to support the proliferation of single purified B cell progenitors.

Interleukin 7 (IL-7) was identified and molecularly cloned from one such stromal cell line as a soluble factor able to stimulate the proliferation of stromal cell-dependent pre-B cells. Subsequently, cDNA encoding the receptor for IL-7, which is now known as IL-7R α , was cloned from both human and mouse. Recent evidence demonstrates that IL-7 is an essential molecule for the production of murine B and T cells. Although its role in human B lymphopoiesis is still unclear, it would appear to play a role in T cell production in the human thymus.

Structure of IL-7 and the IL-7 receptor

The cDNA of IL-7 (initially designated lymphopoietin 1) was first cloned from the murine stromal

cell line IXN/A5. Subsequently, human IL-7 cDNA was cloned from the human hepatoma cell line SK-HEP-1. Murine IL-7 consists of 154 amino acid (aa) residues including a 25 aa signal peptide, whereas human IL-7 is 19 aa longer. This difference in size is due to the absence of an exon in the mouse gene, which corresponds to the 5th exon of the human IL-7 gene. Because of this deletion, murine IL-7 has two N-linked glycosylation sites in contrast to three in human IL-7. However, as deletion of these 19 aa from the human IL-7 molecule has no effect on its biological activity, this region is not essential. Except for this 19 aa region, human and mouse IL-7 are homologous and their overall homology in nucleotide sequence is 81% in the coding region. Both contain three intramolecular disulfide bridges. Although no significant sequence homology has been found with other cytokines, a structural model predicted from the amino acid sequence suggests that its tertiary structure is similar to that of IL-2, IL-4 and granulocyte-macrophage colony-stimulating factor (GM-CSF) in that it has four α helices connected by long crossing loops.

Human IL-7R α was cDNA cloned from a lung cancer cell line which bound recombinant IL-7, and the murine homolog was cloned from a pre-B leukemia cell line by using human IL-7 cDNA. Both encode 439 aa peptides and consist of extracellular, transmembrane and cytoplasmic regions. The presence of two fibronectin type III domains and a WSXWS motif indicates that this is a member of the cytokine receptor family. Although no domains with apparent enzymatic activity have been found in the cytoplasmic region, it shares a number of common motifs such as a box, acidic and serine-rich regions with other cytokine receptor family molecules. Evidence indicates that these regions play an important role for signaling through association with various other molecules. The homology between human and mouse IL-7R α is about 60% at the amino acid sequence level, and human recombinant IL-7 is able to bind and stimulate the murine IL-7R α .

While IL-7R α alone can bind recombinant IL-7, it functions only in association with another cytokine receptor molecule, IL-2R γ (γ c). Indeed, a monoclonal antibody against γ c inhibited, though not completely, IL-7 binding to the receptor complex, suggesting a close association of the two molecules upon IL-7 stimulation.

Tissue expression of IL-7 and IL-7R α

Varying levels of IL-7 mRNA expression are detected in spleen, thymus, kidney, gut epithelium and liver. Unexpectedly, its expression level in the bone mar-

row is low. As no *in situ* hybridization result is available in these tissues, its expression at the cellular level is still unclear. *In vitro* IL-7 expression in stromal cell lines correlates well with their ability to support B lymphopoiesis. Addition of recombinant IL-7 restores the B lymphopoiesis supporting ability of a stromal cell line that does not express IL-7.

The stage-specific expression of the receptor during both B and T cell differentiation has been characterized in the mouse using an IL-7R α -specific monoclonal antibody (mAb) (Figure 1). During B cell differentiation, IL-7R α is expressed through pro-B and pre-B cell stages until surface μ chain is produced. Exact timing of its expression is not clear, but evidence suggests that the earliest B220⁺ progenitors do not express it, indicating that its expression may take place after commitment to the B cell lineage. IL-7R α expression has never been detected in mature surface μ ⁺ B cells in bone marrow nor in peripheral lymphoid organs. On the other hand, it is expressed in both mature and immature T cells. In thymus, IL-7R α expression is found in CD4⁺CD8⁻ (double negative), CD4⁺CD8⁺, CD4⁻CD8⁻, but not in CD4⁺CD8⁺ (double positive) populations. Among double negative immature T cells, IL-7R α expression is believed to correlate well with *c-kit* expression in the CD44⁺CD25⁻ population. Indeed, in the fetal thymus containing only nascent T lineage cells, most of them are IL-7R α ⁺ and γ c⁺. Although IL-7R α expression has also been detected in human T and B lymphocytes, it remains to be determined if the pattern of expression, particularly during early differentiation, is the same as that in the mouse.

Function and signal transduction

In complete agreement with the expression pattern of IL-7R α , blocking of IL-7 or IL-7R α functions results in defective production of lymphocytes but the animals otherwise remain normal. In IL-7 or IL-7R α null mutant mice, B cell genesis is blocked at the pro-B and pre-B stage, though some leakage into mature B cells does exist. Interestingly, the pro-B cell stage is reduced more in IL-7R α (-) than IL-7(-) mice, suggesting the presence of another molecule that can substitute IL-7 at the pro-B stage. Identification of this molecule in a thymic stromal cell clone was recently reported. Likewise, thymic cellularity is markedly reduced in IL-7 or IL-7R α null mutant mice. In the thymus of IL-7R α null mice, CD44⁺CD25⁻ double negative cells increase, while later stages including CD44⁺CD25⁺ double negative cells are reduced, suggesting a requirement for IL-7 signaling during the shift from double negative to double positive T cell populations. In contrast, the

Figure 1 IL-7Rα expression during lymphocyte differentiation in mouse. HSA and CD25 expression of each stage of B and T cell differentiation is indicated. DN, DP and SP represent double negative, double positive and single positive in terms of CD4 and CD8 expression.

proportion of each T cell subset remains relatively unaffected in the IL-7 null mouse, though thymic cellularity is only 5% of normal. This discrepancy in the phenotype of IL-7 and IL-7Rα null mutant mice again suggests the presence of another molecule bound to IL-7Rα, which is now known as TSLP (thymic stromal-derived lymphopoietin). The only lymphoid cell lineage that is not affected in these mice is natural killer (NK) cells.

Although IL-7 can induce the proliferation of human T and B cells *in vitro*, its *in vivo* role in humans is not clear. Two distinct severe combined immunodeficiency (SCID) mutations that have relevance to IL-7 signaling have been reported; one is a mutation in the γ_c gene and the other a mutation in the JAK3 gene. As mentioned previously, an association of IL-7Rα with γ_c is essential for the IL-7 signal. Moreover, as summarized in Figure 2, signal transduction by the IL-7Rα/ γ_c complex requires JAK3 tyrosine kinase. Hence, it is conceivable that a null mutation in either of these genes resulted in defective lymphocyte production. Indeed, mice bearing null mutations of either JAK3 or γ_c genes have severe defects in lymphocyte production. NK cells are also deficient in the γ_c null mouse. As γ_c is also involved in the IL-2, IL-4, IL-9, IL-13, and IL-15

receptors, the difference between the IL-7Rα and γ_c null mice indicates the involvement of one or more of these signals in NK cell production. However, in human, complete loss of JAK3 or γ_c causes a phenotype in which T but not B cell lineages are absent. This indirect evidence indicates that the role of IL-7 signaling in human B lymphopoiesis is redundant.

What is the role of the IL-7 signal in lymphocyte differentiation? Studies on normal pro-B cells indicate that it controls cell cycle progression, particularly entry and maintenance of the S phase. Moreover, evidence suggests that it is involved in stage-specific gene expression such as the VDJ recombinase machinery. As multiple molecules are activated upon stimulation by IL-7, it is conceivable that the IL-7 signal may have multiple functions. Molecules directly associated with the IL-7Rα/ γ_c complex include JAK1, JAK3 and fyn. The phenotype of the JAK3 null mutant mouse strongly suggests that the JAK3 pathway is essential for the induction of cell proliferation. In fact, the activation of JAK3 upon IL-7 stimulation subsequently activates STAT1, STAT5 and phosphatidylinositol 3-kinase (PI3K) through tyrosine phosphorylation. Evidence indicates that PI3K is essential for cell proliferation. However, if and how STAT1 and 5 are involved in

Figure 2 IL-7 signal transduction pathway. Molecules involved in IL-7 signal are depicted schematically. With respect to genes for which mice or human that bear null mutation are available, the phenotypes are given in the corresponding box.

cell proliferation is as yet unclear. Recent studies to reconstitute the IL-7R α signal of IL-7R α (-) pro-B cells by transfecting the receptor genes bearing various mutations indicates that STAT recruitment is not sufficient for the induction of pro-B to pre-B differentiation.

Future questions

While the role of IL-7 in the production of both T and B cells in mouse, particularly in their progenitor stage, is now well established and the biochemical analysis of its signal pathway is in progress, two major questions remain for future study. One is the role of IL-7 in human B lymphopoiesis. If the signal transduction pathways of human IL-7 use the same intracellular machinery as in mouse, the fact that B cell genesis continues in γc or JAK3-deficient patients

suggests the IL-7 signal is not required for the generation of human B cells. This, in turn, raises the question of which molecule(s) are required in humans.

The other major question is the role of IL-7 signaling in mature T cells. Because half of the T cells in peripheral lymphoid organs express IL-7R α , it is reasonable to assume that IL-7 may be involved in the stimulation of mature T cells. Because of the severe lymphopenia in the IL-7 or IL-7R α null mutant mice, however, this question has not yet been addressed in an appropriate way.

Partially purified interleukin 1 (IL-1) and tumor necrosis factor (TNF) were claimed to be directly chemotactic for neutrophils in the early 1980s. However, recombinant IL-1 and TNF lacked leukocyte chemotactic activities *in vitro* although they induce leukocyte infiltration upon intracutaneous injection. This led to the discovery of a neutrophil chemotactic factor distinct from IL-1 and TNF. The cytokine was purified from lipopolysaccharide (LPS)-stimulated human peripheral blood mononuclear cells (PBMC)-conditioned media and was initially termed monocyte-derived neutrophil chemotactic factor (MDNCF). The cDNA cloning of MDNCF revealed that it was identical to 3-10C, which was reported by Schmidt and Weissmann as a gene inducible in enterotoxin-stimulated human PBMC. Subsequently, a biochemically identical cytokine was reported by several groups and termed granulocyte chemotactic peptide (GCP), neutrophil-activating factor (NAF), and neutrophil-activating peptide 1 (NAP-1). Moreover, Larsen and colleagues detected a T lymphocyte chemotactic factor present in phytohemagglutinin (PHA)-stimulated human PBMC-conditioned media that was identical to MDNCF. Since MDNCF has multiple target cells and is produced by various types of cells, it was renamed interleukin 8 (IL-8).

Biochemical properties

Interleukin 8 is synthesized as a precursor (99 amino acids) and processed to a mature secreted form (72 amino acids). In addition to a truncated form (69 amino acids) which is as potent as the mature IL-8, intermediately processed forms (79 and 77 amino acids) with weaker activities have been purified from culture supernatants. The mature IL-8 is not glycosylated and contains four cysteine residues. Due to the existence of many basic amino acids (lysines and arginines), the isoelectric point of mature IL-8 is

>8.5. The sequence Lys–Phe–Leu–Lys–Arg at the C-terminal region is the most probable heparin-binding site. Two intermolecular disulfide bonds are formed between Cys7–Cys34 and Cys9–Cys50. A triple-stranded β sheet is formed between residues 7 and 54, while an α helix is formed in the C-terminal region. The sequence of Glu4–Leu5–Arg6 and the residues near the turn at His33 are presumed to be important for binding to the receptor. At high concentrations, IL-8 dimerizes through formation of hydrogen bonds between the first β strand (residues 23–29) in each molecule. However, a mutant IL-8 protein, which cannot dimerize, still possesses neutrophil chemotactic activity, suggesting that dimerization is dispensable for biological activities.

The IL-8 gene family and related molecules

Since the discovery of IL-8, more than 20 similar cytokines have been identified (Figure 1). These cytokines contain four cysteine residues at the well-conserved positions with a molecular mass of around 8 kDa and possess the ability to attract and activate various types of leukocytes. Hence, the term 'chemokines' was proposed for this novel class of cytokines.

Chemokines can be subdivided into two subclasses, depending on whether the first pair of cysteine residues are separated by one amino acid (CXC) or adjacent (CC). The genes for CXC and CC chemokines reside on human chromosome 4q12–13 and 17q11–12, respectively. CC chemokine, platelet factor 4 and platelet basic protein genes consist of three exons and two introns, whereas the other CXC chemokine genes have an additional exon and intron. However, the similarity of the splice junction and of the sizes of the introns and exons suggest that they all stem from a common ancestral gene.

Production and gene expression of IL-8

Various stimuli, including LPS, proinflammatory cytokines and viruses, induce IL-8 mRNA very rapidly in a variety of cells, including PBMCs, fibroblasts, endothelial cells and keratinocytes. The activation of gene transcription as well as stabilization of its mRNA are responsible for the accumulation of IL-8 mRNA.

IL-8 genomic DNA consists of four exons and three introns. The transcription of IL-8 gene requires, in a cell type-specific manner, the activation of three *cis* elements in the 5'-flanking region of the IL-8 gene: AP-1 (-126 to -120 bp), NF-IL6 (-94 to -81 bp), and NF κ B binding sites (-80 to -70 bp). NF κ B is the most crucial transcription factor and activates IL-8 gene transcription in cooperation with NF-IL6 or AP-1. In addition, several agents such as glucocorticoids, interferon α/β , and FK506, inhibit IL-8 gene transcription by interfering with the activation of NF κ B.

The IL-8 receptor and signaling pathway

Two types of human IL-8 receptor, type A and B, have been identified molecularly. Types A and B consist of 351 and 360 amino acids, respectively (Figure 2). Both belong to a family of G protein-coupled receptors with seven transmembrane domains and possess high sequence homology with each other at the amino acid level, reaching more than 80% homology except for their N-terminal portion. Both genes map to chromosome 2p35 and are accompanied by one pseudogene.

Cells transfected with type A IL-8 receptor cDNA bind only IL-8 with a high affinity, whereas cells transfected with type B bind gro as well as IL-8 with similar high affinity. The difference in their N-terminal portions accounts for the differences in their specificity. Scanning mutagenesis on type A receptor demonstrates that besides the four cysteine residues, Arg199, Arg203 and Asp265 are important for the overall folding of the receptor. Immunofluorescence analysis reveals a selective and coordinate expression of both types of IL-8 receptors (Table 1) although the functional significance of each receptor has not been fully determined yet.

In addition to these specific receptors on leukocytes, Duffy antigen on erythrocytes, which is the entry site of *Plasmodium vivax*, can bind IL-8 as well as several other chemokines including gro, RANTES and MCAF/MCP-1 with a high affinity.

IL-8 activates pertussis toxin-sensitive and receptor-coupled G proteins including $G\alpha_{14}$, $G\alpha_{16}$, $G\alpha_{12}$ and $G\alpha_{i3}$. G proteins, upon conversion to the GTP-bound form, activate phospholipase C β_2 (PLC β_2), RhoA and phosphatidylinositol 3-kinase (PI3K) (Figure 3). Activation of PLC β_2 results in the generation of inositol 1,4,5-triphosphate (IP $_3$). IL-8 also stimulates phosphatidylinositol 4-phosphate kinase (PIP-K), which synthesizes phosphatidylinositol 4,5-bisphosphate (PIP $_2$), the source of IP $_3$. The IP $_3$, in turn, induces the release of Ca $^{2+}$ from intracellular stores, which is sufficient to induce exocytosis and respiratory burst. RhoA, upon conversion to the GTP-bound form, activates a serine-threonine kinase, protein kinase N (PKN) and enhances leukocyte

Figure 2 Alignment of the amino acid sequences of type A (upper) and type B (lower) human IL-8 receptors. Extracellular domains are indicated by bars and numbered from the N-terminal end. The positions occupied by conserved sequences are indicated by filled boxes.

CD16 ⁺ lymphocytes	+	+
CD8 ⁺ lymphocytes	+	+
CD4 ⁺ lymphocytes	-	-
CD20 ⁺ lymphocytes	-	-
Monocytes	+	+
CD34 ⁺ progenitor cells	-	-

adherence through integrins. Activation of PI3K eventually activates ras/raf/mitogen-activated protein kinases (MAPK), resulting in granule release and neutrophil adherence. Moreover, IL-8-induced MAPK activation is negatively regulated by RGS (regulator of G protein signaling).

***In vitro* biological activities**

The actions of IL-8 on neutrophils are diverse (Figure 4): chemotaxis, transendothelial migration with concomitant shedding of leukocyte adhesion molecule 1,

induction of lysosomal enzyme release, respiratory burst, shape change and generation of superoxide anions. Moreover, IL-8 induces chemotaxis of T and B lymphocytes, IL-2-activated natural killer cells, basophils and eosinophils if primed with either IL-3 or granulocyte-macrophage colony-stimulating factor (GM-CSF). IL-8 inhibits IL-4-induced immunoglobulin E (IgE) production by normal B lymphocytes and inhibits *in vitro* colony formation from human bone marrow progenitor cells.

IL-8 has profound effects on nonleukocytic cells. IL-8 is haptotactic (induces cell migration to cell surface- or matrix-bound gradient), and promotes adhesion and proliferation of melanoma cells. It inhibits collagen expression in synovial fibroblasts and enhances cytomegalovirus replication in lung fibroblasts. Furthermore, IL-8 induces the migration of human umbilical vein endothelial cells *in vitro* and angiogenesis in rat cornea.

The roles of IL-8 in experimental animal models

Systemic injection of IL-8 induces a transient granulocytopenia followed by granulocytosis in several animals, including humans. Moreover, it also

Figure 3 Proposed IL-8 receptor-mediated signaling mechanisms.

Figure 4 *In vitro* biological activities of IL-8.

causes a rapid (<30 min) mobilization of bone marrow stem cells into the peripheral blood in mice and primates. Intradermal injection of IL-8 induces a rapid and concentration-dependent neutrophil infil-

tration and neutrophil-dependent plasma leakage at the injected sites. In addition to neutrophils, local injection of IL-8 at a lower dose induces lymphocyte migration to the injected sites. In guinea pigs,

intravenous and intraperitoneal injections of IL-8 causes eosinophil accumulation in skin and lung, respectively.

Administration of neutralizing antibodies to IL-8 prevented neutrophil-dependent tissue injuries observed in several experimental models including lung perfusion injury, LPS-induced acute dermatitis, LPS- or IL-1-induced acute arthritis, immune complex-mediated acute glomerulonephritis, immune complex-mediated pneumonia, and aspiration pneumonia. These observations may implicate IL-8 as one of the major mediators of acute inflammation.

IL-8 transgenic mice (with expression of the transgene directed to either the liver or the gastrointestinal tract) exhibit increases in serum IL-8 levels and circulating neutrophil number, and decreases in L-selectin expression on the surface of neutrophils. They show an accumulation of neutrophils in the microcirculation of the lungs, liver and spleen without neutrophil extravasation, plasma exudate and tissue damage. No apparent change is observed on the bone marrow of the transgenic mice compared with the control littermates. However, neutrophil migration into the inflamed peritoneum is severely impaired in the transgenic mice.

Targeted disruption of the murine IL-8 receptor homolog gene (which has a high of homology with both the type A and type B human IL-8 receptors) results in lymphadenopathy due to an increase in B cells. Serum IL-6 level is also increased in IL-8 receptor-deficient mice. There is an increase in bone marrow cellularity composed of the normal myeloid cells in addition to splenomegaly resulting from an increase in myeloid cells in splenic white pulp. Neutrophil migration into the inflamed peritoneum is severely reduced although neutrophils retain their normal ability to kill bacteria. It should be noted that IL-8 receptor deficient mice, if kept in germ-free environments, do not develop increased myelopoiesis, splenomegaly or lymphadenopathy.

Clinical relevance and possible clinical application of IL-8

Increases in IL-8 protein levels in body fluids has been reported in various types of diseases which are accompanied by neutrophilia and/or neutrophil infiltration into lesions (Table 2). Urinary IL-8 levels increase in several types of glomerulonephritis where neutrophil infiltration is observed, and reflect the disease activity of these types of glomerulonephritis. IL-8 levels in bronchoalveolar fluids are reported to predict the complication of the adult respiratory distress syndrome (ARDS) in patients at risk. Thus, the

determination of IL-8 levels may be a useful tool to monitor some disease activities.

The ability of IL-8 to rapidly mobilize bone marrow stem cells into the peripheral blood may prove helpful for peripheral blood stem cell transplantation. Since neutralizing antibodies to IL-8 prevent tissue injuries observed in several models of inflammation, the development of antagonists at the receptor level, inhibitors at the postreceptor level, or inhibitors of IL-8 production will be important for the treatment of neutrophil-mediated inflammation.

INTERLEUKIN 9 AND ITS RECEPTOR

Yu-Chung Yang, Departments of Medicine (Hematology/Oncology) and Biochemistry/Molecular Biology and Walther Oncology Center, Indiana University School of Medicine, Indianapolis, Indiana, USA

Interleukin 9 (IL-9) was originally described in the mouse system as a T cell growth factor (TCGF P40) which could support the antigen-independent proliferation of certain murine T helper cell clones. Human IL-9 cDNA, on the other hand, was initially isolated based on its ability to stimulate the proliferation of a human megakaryocytic leukemic cell line. Subsequent studies have indicated that IL-9 has a broad spectrum of biological activities within the hematopoietic, lymphopoietic and neuronal systems. The sharing of the common signal transducer among IL-9, -2, -4, -7, and -15 receptors has provided, at least in part, the explanation for the biological redundancy and pleiotropy of these cytokines.

Molecular biology of IL-9 and IL-9R

Both mouse and human IL-9 cDNAs contain a single long open reading frame of 432 nucleotides, which encodes a 144 amino acid polypeptide with an 18 amino acid signal sequence. They also contain four N-linked glycosylation sites, which is consistent with

the extensive size heterogeneity of IL-9 protein observed with IL-9-expressing cells. The overall homology between mouse and human IL-9 cDNAs is 67% at the nucleotide level and 56% at the amino acid level. The human IL-9 gene has been mapped to the long arm of human chromosome 5 while the mouse IL-9 gene has been localized to mouse chromosome 13. Both genes are 4 kb in length and consist of five exons and four introns. The 5'-flanking region of the IL-9 gene contains several potential transcriptional control elements. It has been shown recently that the cooperation of different transcriptional factors including NFκB, *c-jun* and a 35 kDa protein is essential for the constitutive and induced human IL-9 gene expression in human T lymphotropic virus type I (HTLV-I) transformed T cells. Although no IL-9 message can be detected in freshly isolated human peripheral blood mononuclear cells, T cell mitogens such as phytohemagglutinin (PHA) or anti-CD3 induced substantial IL-9 expression that can be further enhanced by phorbol myristate acetate (PMA) or CD28. In the mouse system, IL-9 is mainly

produced by T_H2 clones *in vitro*, and *in vivo* IL-9 production is also associated with T_H2-like T cell responses.

The mouse IL-9R encodes a 468 amino acid polypeptide with two potential N-linked glycosylation sites and six cysteine residues in the extracellular domain. The position of these cysteine residues, the presence of a WSEWE motif in the extracellular domain and the lack of consensus sequences for tyrosine or serine/threonine kinases in the intracellular domain suggest that IL-9R is a member of the hematopoietin receptor superfamily. The human IL-9R encodes a 522 amino acid polypeptide with 53% homology with the mIL-9R. The extracellular region of human and mouse IL-9R is well conserved while the intracellular domain is quite different between the two. Despite the high sequence homology of ligand and receptor between the two species, mouse IL-9 interacts with mouse and human IL-9R while human IL-9 only targets human but not mouse cells. Mouse IL-9R gene is a single-copy gene composed of nine exons and eight introns, on the other hand, the human genome contains at least four IL-9R pseudogenes with 90% homology with the IL-9R gene. Some of the molecular characteristics of IL-9 and its receptor are summarized in Table 1.

Signal transduction mechanisms of IL-9

Because of the overlapping biological activities and the sharing of IL-2R γ chain as common signal transducer of IL-9 and other cytokines such as IL-2, -4, -7 and -15, many investigators have compared the signal transduction pathways mediated by this group of cytokines. These studies indicated that there are convergent and divergent points along the signaling pathways mediated by these cytokines. Figure 1 summarizes some of the signaling events mediated by IL-9 in hematopoietic cells.

Although most of hematopoietin receptors do not possess tyrosine kinase activity, it appears that protein tyrosine phosphorylation plays an important role in growth factor-mediated signal transduction. It has been shown that IL-9 stimulation of different IL-9 responding cells results in enhanced tyrosine phosphorylation of proteins of different molecular weights. Some of the tyrosine kinases involved in the process are believed to be members of the JAK (Janus kinase) family of nonreceptor tyrosine kinases, which have been shown to play important roles in signaling pathways mediated by different cytokines. It was found that JAK family kinases, such as JAK1 and JAK3, can physically associate with receptor complexes and are tyrosine phosphorylated and activated following stimulation with IL-9 and other related

cytokines. Although common JAKs are activated by IL-9 and related cytokines, the cytokine specificity may in part be determined by downstream signaling molecules such as IRS proteins (insulin receptor substrate 1 or 2) and STATs (signal transducers and acti-

vators of transcription). IRS proteins contain multiple tyrosine residues which may serve as substrates for upstream kinases and as docking sites for the SH2 domains of Grb2, SHP-2, Nck and PI3K. It is believed that the ability of IRS proteins to interact with different downstream molecules following cytokine stimulation may determine part of cytokine specificity. IL-9 and related cytokines have also been shown to activate different members of the STAT family transcriptional factors. In addition, differences have also been observed among primary response genes activated by IL-9 and related cytokines. These studies strongly suggest that the specificity for IL-9 and related cytokines could be achieved through the unique tyrosine phosphorylated proteins, their associated molecules, specific transcriptional factors and primary response genes triggered by individual cytokines.

Biological activities of IL-9

IL-9 is a T cell-derived cytokine with a variety of *in vitro* biological activities within the hematopoietic, lymphopoietic and neuronal systems. Some of the biological activities known to be associated with IL-9 are summarized in Table 2.

T cell growth factor activity of IL-9

IL-9 was originally discovered based on its ability to support the growth of certain mouse helper T cell clones. Subsequent studies have shown that this cytokine does not appear to function as a general growth factor for T cells. In fact, freshly isolated T cells do not respond to IL-9 even in the presence of costimuli such as lectins or anti-CD3 antibodies. Fetal thymocytes, on the other hand, can proliferate in response to the combination of IL-2 and IL-9, implicating the role of IL-9 in T cell ontogeny in the thymus. It appears that IL-9 responsiveness correlates with the

activation status but not the phenotype of T helper clones.

Mast cell-enhancing activity of IL-9

Several studies have shown that mouse IL-9 possesses mast cell-enhancing activity (MEA) and can enhance the mast cell growth elicited by IL-3 and IL-4. It not only provides a proliferative signal, but also leads to a marked functional activation of responsive mast cells as evidenced by the production of IL-6 and the expression of mast cell proteases and the α chain of the high-affinity IgE receptor. Interestingly, IL-9 overexpression in transgenic mice results in a massive intestinal mastocytosis and increased circulating levels of mast cell specific proteases.

Erythroid burst-promoting activity of IL-9

Human IL-9 can support erythroid colony formation (BFU-E) in cultures supplemented with erythropoietin using CD34⁺ progenitors for human bone marrow, peripheral and cord blood. The colony-enhancing effect elicited by human IL-9 is erythropoietin-dependent although IL-9 alone sustains the survival of erythroid progenitor cells *in vitro* as assessed by the delayed addition of erythropoietin to the cultures. It has also been shown that IL-9 does not accelerate cycling of adult or fetal BFU-E, CFU-Mix or CFU-GM to the extent observed after incubation with IL-6. In contrast to its maturation activity on adult erythroid progenitors, IL-9 has a wider spectrum of action on fetal progenitors and, when combined with IL-3 and granulocyte-macrophage colony-stimulating factor (GM-CSF), results in clonogenic maturation of progenitors that do not undergo maturation after stimulation with IL-3 and GM-CSF. The erythroid burst promoting activity has also been ascribed to mouse IL-9.

Biological effects of IL-9 on B cells

IL-4 has been shown to induce immunoglobulin E (IgE) production by normal B lymphocytes from human peripheral blood without preactivation of these cells. In the absence of IL-4, IL-9 does not induce IgE and IgG production by human B lymphocytes. However, in the presence of a suboptimal dose of IL-4, IL-9 markedly enhances IgE and IgG production in a dose-dependent manner. The ability of IL-4 to induce IgG and IgM by purified B lymphocytes preactivated with *Staphylococcus aureus* Cowan strain I was also enhanced in the presence of IL-9. These results implicate a role for IL-9 in the regulation of immunoglobulin production by B lymphocytes.

Table 2 *In vitro* biological activities of human and mouse IL-9

Human IL-9

- supports erythroid colony formation
- synergizes with IL-4 in the production of IgE and IgG by B cells
- supports the growth of certain H-RS cells

Mouse IL-9

- supports the growth of certain helper T cell clones
- stimulates erythroid colony formation
- induces fetal thymocyte proliferation in combination with IL-2
- enhances mast cell growth elicited by IL-3 or IL-4
- promotes maturation of mouse embryonic hippocampal progenitor cell lines in combination with TGF α and bFGF

Biological effects of IL-9 on neuronal cells

In combination with transforming growth factor α (TGF α) and basic fibroblast growth factor (bFGF), IL-9 has been shown to promote neuronal morphological maturation of mouse embryonic hippocampal progenitor cell lines, as evidenced by enhanced neurite outgrowth and nuclear enlargement, induced expression of high molecular weight mature neurofilament protein and reduced expression of nestin and NF66. In addition, neuronal cells thus treated can also give action potentials sensitive to tetrodotoxin, which is indicative of sodium channels with more mature physiological properties.

Potential role of IL-9 in leukemia and lymphoma

Since T cell-stimulating activity of IL-9 depends on the activation status but not the phenotype of T cells and the fact that transfection of IL-9-dependent cells with IL-9 cDNA resulted in autonomous growth and tumorigenicity of these cells, Renauld and coworkers have hypothesized that T cell transformation may in part be due to the dysregulated expression of IL-9. To test this hypothesis, transgenic mice expressing high levels of IL-9 constitutively were generated. Although no major morphological changes were noted in the lymphoid organs of most mice, the animals showed a high incidence of thymic lymphomas, were highly susceptible to chemical mutagens, and exhibited a high sensitivity to the tumorigenic effect of gamma irradiation. These results support the notion that dysregulated expression of IL-9 may 'prime' T cells to a transformed state that is more susceptible to secondary transforming agents such as mutagens or irradiation.

It is known that certain mouse helper T cell clones can proliferate in response to cytokines such as IL-2, -4 or -9 in the absence of antigen-presenting cells and antigen stimulation. Although dexamethasone, a glucocorticoid hormone, was able to induce apoptosis in these cells, the inhibition of IL-2-induced proliferation was found not to be the result of apoptosis, because this process can be antagonized by IL-2 as well as IL-4 and IL-9. These results indicate that different signaling events may be involved in growth stimulation and inhibition of apoptosis in the presence of glucocorticoids. IL-9 has also been shown to be more potent in protecting mouse thymic lymphomas against apoptosis than inducing cell proliferation. The antiapoptotic effects of IL-9 may explain certain aspects of its role in leukemogenesis but may also have potential therapeutic usage in certain clinical settings.

To examine whether IL-9 may be involved in the pathogenesis of human lymphomas, Mertz and colleagues have analyzed the expression of IL-9 in a variety of tumors and found that IL-9 message was detected in several cases of large cell anaplastic lymphoma (LCAL) and Hodgkin's disease (HD). It has been shown that primary and cultured Hodgkin's Reed-Sternberg (H-RS) cells can coexpress IL-9 and IL-9R. The possible role of IL-9 in the pathogenesis of HD was also suggested based on the inhibition of cultured H-RS cell growth in the presence of antisense oligonucleotides and antibodies to IL-9. Recent studies have also shown a cooperative effect of IL-9 and CD40 ligand in promoting the clonogenic growth of certain HD cell lines. The possible involvement of IL-9 as an autocrine growth factor or in concert with surface antigens for some human lymphomas requires further investigation.

INTERLEUKIN 10 AND ITS RECEPTOR

Vijay P Khatri, Division of Surgical Oncology, Roswell Park Cancer Institute, Buffalo, New York, USA

Michael A Caligiuri, Department of Hematology/Oncology, Arthur G. James Comprehensive Cancer Center, Ohio State University Medical Center, Columbus, Ohio, USA

Interleukin 10 (IL-10) is an important immunoregulatory cytokine which was initially known as the cytokine synthesis inhibiting factor (CSIF) and its discovery was based upon characterization of its biological activity. Fiorentino described a type 2 T helper (T_H2) cell-derived factor that could selectively inhibit the secretion of interferon γ (IFN γ) by type 1 T helper (T_H1) cells. Murine Ly-1⁺ B cell lymphomas were shown to have a 'B cell-derived growth factor' activity that strongly enhanced IL-2- or IL-4-dependent thymocyte proliferation. O'Garra demonstrated that the same murine lymphoma supernatant also had mast cell growth factor activity. Based on these biological activities, cDNA encoding mouse IL-10 (mIL-10) was isolated from an concavalin A-activated T_H2 clone. Subsequently, the human IL-10 (hIL-10) was identified by screening a tetanus toxin-specific human T cell cDNA library using probes based on the mouse cDNA sequence.

18.5 kDa acid-sensitive protein that belongs to the four α -helical bundle cytokine superfamily. Unlike murine IL-10, which is glycosylated at the N-terminus, hIL-10 lacks detectable carbohydrate moieties. This N-linked glycosylation is, however, not necessary for its biological activity. Both mIL-10 and hIL-10 protein contain intrachain disulfide bonds that are essential for the biological activity of this cytokine. hIL-10 has been shown to be active on both murine and human cells, but mIL-10 is not active on human cells. Interestingly, both the mIL-10 and hIL-10 exhibit a strong DNA (71%) and amino acid sequence (84%) homology to the open reading frame in the Epstein-Barr virus (EBV) genome called BCRF-1. Since hIL-10 and BCRF-1 (viral IL-10) are closely related in the amino acid sequence, it is postulated that EBV may have captured this mammalian gene during evolution to confer survival advantage.

Physical properties of IL-10

The mIL-10 and hIL-10 cDNAs clones exhibit a high degree of nucleotide sequence homology (>80%) and also encodes very similar (>73% homology) open reading frames of 178 amino acids. Murine IL-10 is a homodimeric cytokine with an apparent molecular weight of 35 kDa due to the mixture of 17, 19 and 21 kDa polypeptides. Human IL-10 is a

IL-10 gene structure

The gene for both the murine and human IL-10 has been located to chromosome 1 and is present as single copies in the genome. The mIL-10 gene contains five exons spanning over 5.1 kb of the genome with a similar structure determined for human IL-10. IL-10 gene transcription produces a single mRNA of 1.4 kb in mouse and 2 kb in humans. Transcriptional

regulation of IL-10 is still unclear though its upstream regulatory sequence elements closely resemble that of IL-6. Transcriptional control is the predominant feature in regulating IL-10 levels in T lymphocytes and appears to involve cyclosporine-resistant pathways. Furthermore, regulation of post-transcriptional mRNA stability/degradation also seems to be an important feature which in part may be mediated via the multiple copies of the AUUUA motifs present within the 3'-untranslated region (3'-UTR). Similar regulatory mechanisms may also be operative in monocytes and B lymphocytes.

Cellular source of IL-10

IL-10 is produced by several types of cells, including activated T lymphocytes, monocytes, B cells as well as nonhematopoietic sources such as keratinocytes, colon carcinoma and melanoma cells. In humans though T_H2 T cell clones are the main source of IL-10, many T_H1 clones will also secrete IL-10 following antigen-specific stimulation. In contrast, mIL-10 is produced by the T_H2 subset of $CD4^+$ T cells but not by T_H1 or $CD8^+$ T cells. In humans both $CD4^+$ and $CD8^+$ T cells secrete IL-10 following stimulation with anti-CD3, although significantly higher levels are produced by $CD4^+$ T cells. Among the $CD4^+$ T cells, $CD45RO^+$ memory cells produce 10-fold higher level of IL-10 than naive T-cells ($CD45RA^+$). Murine Ly-1 B cells as well as Epstein-Barr virus transformed human B cells produce IL-10. Human monocytes are also a major source of IL-10 in response to activation with lipopolysaccharide. Interestingly, kinetics studies reveal that IL-10 is synthesized later than other immunoregulatory cytokines by activated T cells or monocytes. This suggests that IL-10 may play a regulatory role for the later phases of the immune response.

Effect of IL-10 on the immune system

Like most other cytokines, IL-10 exerts multiple effects upon the function of various cell lineages including lymphocytes, monocytes, natural killer (NK) cells, and dendritic cells.

T lymphocytes

In the mouse, IL-10 specifically inhibits T_H1 cell cytokine synthesis ($IFN\gamma$ and IL-3) particularly when macrophages were used as antigen-presenting cells (APCs). IL-10 has been demonstrated to have inhibitory effects on the proliferation, survival and cytokine production of human T cells. In humans, direct interaction of IL-10 with the IL-10 receptor (IL-10R) on T cells results in specific suppression of IL-2 gene

transcription thus inhibiting T cell proliferation. Since presence of IL-10 also reduces the expression of IL-2R on T cell clones, exogenous IL-2 cannot completely overcome the inhibition produced by IL-10. T Cells are also indirectly inhibited by IL-10 through alteration of the antigen-presenting function of monocytes. IL-10 accomplishes this effect by downregulating the expression of major histocompatibility complex (MHC) class II antigen on monocytes thus decreasing the peptide/MHC complexes available for interaction and adequate stimulation of T cells. Besides the effects on $CD4^+$ T_H1 cells, IL-10 also inhibits $IFN\gamma$ synthesis by $CD8^+$ T cells without affecting their cytotoxic function. In contrast to these inhibitory effects, IL-10 also has positive effects where it can promote survival of IL-2-starved T cells which otherwise are destined to undergo apoptosis. hIL-10 has also been shown to stimulate chemotaxis, proliferation, differentiation and cytolytic activity of human $CD8^+$ T cells.

Macrophage/monocytes

Experimental evidence indicates that monocytes/macrophages are the prime targets of IL-10 and has prominent effects on their morphology, phenotype and cytokine production. Besides causing de-adherence and rounding up of monocytes, IL-10 also strongly inhibits their constitutive and inducible expression of MHC class II antigen. IL-10 also has the ability to block B7 and ICAM-1 expression in monocytes in response to $IFN\gamma$, thereby disrupting monocyte-T cell interaction. Production of IL-1 α , IL-1 β , IL-6, IL-8, tumor necrosis factor α (TNF α), granulocyte-macrophage (GM-) and granulocyte colony-stimulating factor (G-CSF) by human monocytes following activation is inhibited by IL-10 at the mRNA and protein level. IL-10 also prevents IL-12 expression from monocytes, thereby inhibiting T_H1 cell development. Furthermore, IL-10 inhibits its own production by monocytes indicating the presence of a self-regulatory negative feedback loop.

Natural killer (NK) cells

IL-10 can inhibit monocyte-induced NK cells production of $IFN\gamma$. IL-10 has this effect on NK cells indirectly by suppressing monocyte production of IL-12. However production of $IFN\gamma$, TNF α and GM-CSF by IL-2-activated NK cells is significantly enhanced by IL-10. IL-10 has also been shown to induce significant NK cytotoxic activity against NK-resistant tumor cell targets.

B lymphocytes

Unlike the effects on monocytes, IL-10 induces the

expression of MHC class II antigen on resting B cells. IL-10 leads to enhanced viability of B cells *in vitro* and augments their differentiation into antibody-secreting cells particularly after activation by anti-CD40 antibody. IL-10 synergizes with IL-2 to induce B cell differentiation by upregulating their high-affinity IL-2 receptor. Upon stimulation with polyclonal activators or transformation by EBV, purified B cells will produce IL-10. The ability of B lymphocytes to produce and to respond simultaneously to IL-10 has suggested that this cytokine may act as an autocrine growth factor in humans.

IL-10 receptor

The various biological effects of IL-10 are mediated by engaging with its cell surface receptor. Recently both the murine and human receptors for IL-10 were identified, characterized and cloned. There is 75% DNA sequence homology between the mIL-10R and the hIL-10R, with 60% identity between the predicted amino acid sequence. The hIL-10R gene is located on chromosome 11 and its mRNA expression has been detected in all IL-10-responsive cells (mainly hematopoietic cells). Binding studies of radioiodinated hIL-10 to various human cell lines characterized the hIL-10 receptor to be a 110 kDa glycoprotein. As mentioned earlier, hIL-10 will bind to both murine and human IL-10 receptors, whereas mIL-10 binds only to mIL-10R. Major differences in the N-terminal third of mIL-10 and hIL-10 protein may be in part responsible for the apparent species specificity.

Structural analysis reveals homology to the class II cytokine receptor gene family which includes the receptors for IFN α/β and γ . This is interesting considering the fact that IL-10 and IFN γ antagonize each other's function. Receptors belonging to the type I and II cytokine receptor families are now known to utilize the JAK/STAT family of proteins for signal transduction. Characterization of mIL-10's intracellular signaling demonstrates that it activates STAT1, STAT3 and STAT5 that subsequently form multiple STAT heterocomplexes and bind to the IFN γ response region (GRR) of the Fc γ R1 gene. STAT3, but not STAT1 or STAT5, is directly recruited to the ligand-activated mIL-10R by binding to a specific tyrosine-containing docking site in the receptor intracellular domain. In human T cells and monocytes, IL-10/IL-10R complex induces phosphorylation of tyk2 and JAK1 with subsequent activation of STAT1 α and STAT3. STAT3 is predominantly activated over STAT1 particularly in monocytes and the subsequent distinct homodimer/heterodimers complex of the two STAT proteins may

explain why T cells and monocytes individualize their response to IL-10. IL-10 has also been shown to mediate monocyte proliferation through selective activation of the phosphatidylinositol 3-kinase and p70 S6 kinase. Thus recent data suggest that multiple and distinct signaling pathways may mediate the various pleiotropic activities of IL-10.

INTERLEUKIN 11 AND ITS RECEPTOR

Yu-Chung Yang, Departments of Medicine (Hematology/Oncology) and Biochemistry/Molecular Biology and Walther Oncology Center, Indiana University School of Medicine, Indianapolis, USA

The cDNA encoding interleukin 11 (IL-11) was originally isolated from a primate bone marrow-derived stromal fibroblast cell line based on its mitogenic activity on an IL-6-dependent mouse plasmacytoma cell line. The same cDNA was also isolated independently by its ability to inhibit adipogenesis. Subsequent *in vitro*, *in vivo* and clinical studies have shown that IL-11 is a multifunctional cytokine important in hematopoiesis. Mouse and human IL-11 receptor (IL-11R) cDNAs have been isolated by hybridization using degenerate oligonucleotides for the WSXWS motifs of hematopoietin receptors and an enhancer-trap method. Sharing of the common gp130 signal transducer among IL-11, IL-6, leukemia inhibitory factor (LIF), oncostatin M (OSM), ciliary neurotrophic factor (CNTF) and possibly cardiotropin 1 (CT-1), at least in part, the biological redundancy and pleiotropy of these cytokines. *In vitro* and *in vivo* studies have implicated IL-11 as a multifunctional growth factor with therapeutic potential in enhancing thrombopoiesis, protecting gastrointestinal injury and modulating immune response. Like many other hematopoietic growth factors its clinical efficacy should be interpreted with caution and may be further improved by combination with other hematopoietic growth factors.

Molecular biology of IL-11 and IL-11R

IL-11 cDNA and genomic sequences are well conserved among different species. IL-11 cDNAs contain a single open reading frame of 199 amino acids with a 21 amino acid signal peptide and a calculated molecular weight of 23 kDa. The cDNA encodes no cysteine residues and no N-linked glycosylation sites. The overall homology between mouse and human IL-11 cDNAs is 88% at the amino acid level and

86% at the nucleotide level. The human IL-11 gene has been mapped to the long arm of human chromosome 19 at 19q13.3–13.4. The gene is 7 kb in length and consists of five exons and four introns. The 5'-flanking region contains several potential transcriptional control elements including AP-1, SP-1 and NF- κ B. There are at least nine copies of ATTTA sequence in the 3'-flanking region. The IL-11 transcripts (2.5 and 1.5 kb) have been detected in primate and human bone marrow-derived stromal fibroblast cell lines, human lung fibroblast, trophoblast, pulmonary and tracheal epithelial, cervical carcinoma, osteogenic sarcoma, megakaryoblastic and other leukemic cell lines. In addition, IL-11 transcripts have also been detected in human chondrocytes, synoviocytes and umbilical vein or adult aortic endothelial cells. The expression of the IL-11 transcripts in different cell types is constitutive but can be attenuated by different positive regulators including IL-1, transforming growth factor β (TGF β), tissue plasminogen activator (t-PA), calcium ionophore, respiratory syncytial virus (RSV), prostaglandin E₁ and E₂ and forskolin, and negative regulators such as retinoic acid, IL-4, dexamethasone and heparin. The mechanisms of IL-11 gene expression mediated by different modulators have been shown to be at either the transcriptional or post-transcriptional level. In stromal fibroblasts, a 10 bp region (5'GGTGAGTCAG3') containing a consensus AP-1 site has been found to be responsible for the basal level transcription of the IL-11 gene and JunD is one of the major components of the DNA-protein transcriptional complexes. The 3'-UTR of IL-11 mRNA can function as a destabilizing component in IL-11 mRNA metabolism, possibly through the AUUUA motifs. In addition, the IL-11 5'-UTR and the IL-11 coding sequence, in conjunction with certain protein

tyrosine kinases, are required for the stabilization of the IL-11 mRNA by IL-1 in stromal cells.

IL-11R consists of at least one ligand-binding subunit (IL-11R α) and a signal transduction subunit (gp130). The mouse and human IL-11R cDNAs encode a 432 and a 422 amino acid polypeptide, respectively, with two potential *N*-linked glycosylation sites and four cysteine residues in the extracellular domain. The position of these cysteine residues, the presence of a WSTWS motif in the extracellular domain and the lack of consensus sequences for tyrosine or serine/threonine kinases in the intracellular domain suggest that IL-11R α is a member of the hematopoietin receptor superfamily. The overall homology between mouse and human IL-11R α is 84% at the amino acid level and 85% at the nucleotide level. In the mouse genome, there are at least two IL-11R α genes, IL11R α and IL11R α 2, that can potentially encode the IL-11R α . The IL-11R α gene is ubiquitously expressed while the IL11R α 2 gene is only expressed in certain strains of mice in specific organs such as testis, lymph node and thymus. It appears that the molecular composition of IL-11R is more complicated than initially anticipated. Further biochemical molecular and *in vivo* knockout studies of IL-11R are underway to dissect the essential components for transducing IL-11 signals. Some of the known biochemical properties of IL-11 and IL-11R α are summarized in Table 1.

Signal transduction mechanisms of IL-11

Because of overlapping biological activities and sharing of the gp130 signal transducer by IL-11R and the receptors for other cytokines such as IL-6, LIF, OSM, CNTF and possibly CT-1, many investigators have compared the signal transduction pathways mediated by this group of cytokines. These studies indicated that there are convergent and divergent points along the signaling pathways mediated by these cytokines. Some of the signaling events mediated by IL-11 in mouse preadipocytes are shown in Figure 1 and summarized below.

Involvement of kinases

Kinases involved in IL-11 signaling include JAK kinases, MAPKs, pp90^{rsk}, Src family kinases and PI3K. JAK (Janus kinase) family nonreceptor tyrosine kinases play important roles in signaling pathways mediated by different cytokines. It was found that JAK family kinases physically associate with gp130 and are tyrosine phosphorylated and activated following stimulation with IL-11 and other IL-6-type cytokines. MAPKs and pp90^{rsk} have been shown to

Figure 1 Possible control mechanisms of IL-11-mediated signal transduction pathways in preadipocytes.

be activated by a variety of growth factors and mitogens. MAPKs and pp90^{rsk} can be activated by IL-11 and related cytokines. pp90^{rsk} is one of the H7-sensitive protein kinases involved in the expression of primary response genes induced by gp130 family cytokines. In addition to pp90^{rsk}, various H7-sensitive kinases may control the expression of primary response genes at either the transcriptional or post-transcriptional level. Src family tyrosine kinases represent an expanding class of closely related intracellular enzymes that participate in the signal transduction pathways of a variety of surface receptors. It has been shown that Src family kinases, such as p60^{src} and p62^{yes} can be activated by IL-11 in mouse preadipocytes. PI3K, which phosphorylates the D3 position of phosphatidylinositol or its derivatives, has been associated with many cellular processes. IL-11-stimulated cells revealed increased PI3K activity and the increased PI3K was found to be associated with tyrosine phosphorylated proteins, including p62^{yes}. The amount of p62^{yes} associated with PI3K transiently increased in response to IL-11. Recent studies have shown that IL-11 induces Grb2 to bind to p59^{fyn} and JAK2.

Involvement of phosphatases

Phosphatases involved in IL-11 signaling include MAPK phosphatase, SHP-2 and PP2A. IL-11 significantly induces expression of the 3CH134 gene, which encodes a phosphatase with dual specificity that can specifically dephosphorylate and inactivate MAP kinases both *in vitro* and *in vivo*. IL-11 has also been shown to stimulate tyrosine phosphorylation of SHP-2, a SH2-containing protein tyrosine phosphatase shown to be important for signaling of different cytokines. The C-terminus of SHP-2 has been shown to associate with several tyrosine phosphorylated proteins including gp130 and JAK2. The association of SHP-2 and gp130 or JAK2 can be further induced by IL-11 stimulation. Peptide competition studies suggest different interactions between SHP-2/gp130 and SHP-2/JAK2. Recent studies have also shown that IL-11 can induce the association of PP2A, PI3K and p62^{yes} to JAK2.

Transcriptional factors involved in IL-11 signaling

STAT (signal transducers and activators of transcription) family transcriptional factors are cytoplasmic proteins which become tyrosine phosphorylated and activated following ligand-receptor interactions and activation of JAK family kinases. STAT1 and associated proteins are tyrosine phosphorylated and translocated to the nucleus following IL-11 treatment in 3T3-L1 mouse preadipocytes. The activation of STAT3 has been demonstrated for other cytokine

receptors within the gp130 family. The activation of primary response genes such as junB and tis11 by IL-11 may require transcriptional factors other than STATs.

Biological activities of IL-11

IL-11 is a bone marrow fibroblast-derived cytokine with a variety of *in vitro* biological activities within the hematopoietic, lymphopoietic, hepatic, adipose, bone and neuronal systems. IL-11 has been tested in various animal models including mice, rats, hamsters, rabbits and nonhuman primates. Some of these *in vitro* and *in vivo* studies are summarized in Tables 2–4. It appears that IL-11 may be a potential therapeutic agent for thrombocytopenia and neutropenia following myeloablative therapy and bone marrow transplantation.

In addition, based on its immunomodulatory activity and ability to maintain the integrity and pro-

Table 2 *In vitro* biological activities of IL-11

Supports the growth of certain plasmacytoma, hybridoma and myeloma cell lines
Enhances the growth of myeloid leukemic cells in combination with IL-3, GM-CSF or SCF
Stimulates increases in numbers, sizes and ploidy values of megakaryocyte colonies in human and murine systems in combination with IL-3 or SCF
Stimulates primitive multilineage hematopoietic progenitors as well as precursors at various stages of erythroid differentiation in combination with IL-3 or SCF
Supports the survival and expansion of primitive progenitor cells in combination with other cytokines
Increases the tritiated thymidine suicide rate of human fetal but not adult CFU-MIX, CFU-GM and BFU-E
Enhances the generation of antigen-specific plaque-forming cells (PFCs) in the <i>in vitro</i> mouse spleen cell culture system
Acts directly on human T (not B) cells, particularly the CD4 ⁺ CD45RA ⁺ T cell subset, to enhance immunoglobulin secretion
Enhances the effects of IL-7 and SCF to differentiate AA4.1 ⁺ B220 ⁺ Mac-1 ⁺ fetal liver progenitor cells
Induces the synthesis of several major human acute phase plasma proteins
Inhibits adipogenesis and the associated lipoprotein lipase (LPL) activity
Induces neuronal maturation of immortalized mouse embryonic hippocampal cell lines
Induces the formation of osteoclasts in mouse bone marrow and calvaria cultures
Stimulates the production of the tissue inhibitor of metalloproteinases in chondrocytes and synoviocytes
Increases the histamine responsiveness of airway smooth muscle cells
reduces the production of proinflammatory cytokines including TNF- α , IL-1 β , IL-6 and nitric oxide (NO).

Table 3 Biological effects of IL-11 in normal animals*Mice*

IL-11 enhances primary and secondary immune responses; increases the absolute numbers of CFU-GM and stimulates CFU-GM, BFU-E and CFU-GEMM progenitor cells to a higher cell cycle rate

IL-11 stimulates megakaryocyte maturation and an increase in peripheral platelet number in normal and splenic mice

IL-11 in combination with G-CSF results in a synergistic increase in splenic cellularity and elevated numbers of CFU-MK, BFU-E, CFU-GM and CFU-S_{day12} and the increased numbers of MK progenitors in the spleen are highly responsive to IL-11 and Epo

Rats

IL-11 alone significantly induces thrombocytosis, and in combination with G-CSF, induces an increased myelopoiesis. Combinations of two early-lineage CSFs (IL-11 + CSF) and a later-lineage CSF (G-CSF) significantly induces new-born rat myelopoiesis and IL-11 alone significantly induces new-born rat thrombopoiesis

Primates

IL-11 has thrombopoietic effects in nonhuman primates when administered by constant intravenous infusion or subcutaneous administration. Megakaryocytes from IL-11-treated monkeys have many ultrastructural characteristics indicative of increased maturation.

IL-11 either alone or in combination with GM-CSF or IL-3 decreases red blood cell counts, hemoglobin and hematocrit; the thrombopoietic effects of the combination of IL-11 and GM-CSF or IL-11 and IL-3 are greater than each cytokine administered alone; IL-11 alone has no effect on leukocyte counts but enhances leukocytosis in response to IL-3 or GM-CSF

mote the healing of the gastrointestinal mucosa, IL-11 can also be used to reduce the severity of chemotherapy-induced mucositis and associated inflammatory complications.

Potential clinical significance of IL-11

Two clinical trials of IL-11 in cancer patients have been performed. In a phase I trial in patients with breast cancer, IL-11 was administered daily for 14 days during a 28-day prechemotherapy "cycle 0". Patients subsequently received up to four 28-day cycles of cyclophosphamide and doxorubicin chemotherapy (day 1) followed by IL-11 (days 3 through 14). The results indicated that IL-11 has thrombopoietic activity at all doses studied (10, 25, 50, 75 and 100 $\mu\text{g kg}^{-1} \text{ day}^{-1}$), is well tolerated at doses lower than 50 $\mu\text{g kg}^{-1}$ and at doses greater than 25 $\mu\text{g kg}^{-1} \text{ day}^{-1}$ has the potential to reduce chemotherapy-induced thrombocytopenia in these patients. The effects of IL-11 were subsequently evaluated in a ran-

domized phase II trial in cancer patients who had previously received platelet transfusions for severe chemotherapy-induced thrombocytopenia. Ninety three patients who had received platelet transfusion for nadir platelet counts less than 20 000 μl during chemotherapy cycle immediately prior to entry into the study were randomized to receive placebo or IL-11 at doses of 25 or 50 $\mu\text{g kg}^{-1}$ subcutaneously once daily for 14 to 21 days beginning one day after chemotherapy. Chemotherapy was continued during the study without dose reduction. The results demonstrated that IL-11 treatment at a dose of 50 $\mu\text{g kg}^{-1}$ significantly reduces the need for platelet transfusion in subsequent chemotherapy cycles for patients who had required platelet transfusions for severe thrombocytopenia in a previous cycle. The thrombopoietic effect of IL-11 is being further evaluated in other phase II and phase III trials.

Summary

IL-11 was originally identified based on its biological similarities to IL-6; these two cytokines, however, are not functionally identical. Identification and characterization of receptor components of IL-11R and the associated signaling molecules will be required to dissect the mechanisms responsible for cytokine specificity. IL-11 is a cytokine with a more restricted spectrum of target cells than IL-6 and this unique property may explain the minimal or no toxicity associated with IL-11 in the *in vivo* studies. *In vivo* administration of IL-11 in normal and myelosuppressed animals has demonstrated the thrombopoietic effect of this cytokine. Phase I and II clinical trials provide further support that IL-11 is an important thrombopoietic agent that can be used safely in patients with severe chemotherapy-induced thrombocytopenia. Because of its immunomodulatory activity and ability to promote healing of the gastrointestinal mucosa, IL-11 may also reduce the severity of chemotherapy-induced mucositis and associated inflammatory complications. These biological activities have led to clinical trials for treatment of chemotherapy-induced mucositis and Crohn's disease. Based on its ability to enhance thrombopoiesis, protect gastrointestinal epithelial injury and reduce inflammatory complications, IL-11 therefore represents a multifunctional cytokine that may potentially offer several benefits in cancer therapy. In addition, IL-11 is being evaluated further in the treatment of various inflammatory disorders such as inflammatory bowel disease, rheumatoid arthritis and sepsis. Future clinical trials with IL-11 alone and in combination with other biologic, radiation or

Table 4 Biological effects of IL-11 in experimentally induced animal models**HEMATOPOIETIC EFFECT***(a) Mice immunosuppressed by cyclophosphamide*

IL-11 augments the number of spleen antigen-specific PFC as well as serum antigen-specific antibody titers, and decreases the time required to regain normal levels of leukocyte and platelet counts

(b) Mice myelosuppressed by nitrosourea

IL-11 diminishes nitrosourea-induced pancytopenia and leads to a significant reduction in chemotherapy-related mortality. The increase in multilineage peripheral blood counts is associated with a higher number of committed progenitor cells and HPP-CFC in the bone marrow

(c) Mice myelosuppressed by combined sublethal irradiation and carboplatin

IL-11 accelerates the recovery of peripheral platelet, red blood cell counts and hematocrit

(d) Mice receiving syngeneic bone marrow transplants or sublethal irradiation

IL-11 increases peripheral platelet and leukocyte (acceleration of neutrophil recovery) counts

(e) Mice receiving syngeneic bone marrow infected with IL-11-expressing retrovirus and lethal irradiation

The IL-11 expressing mice have an accelerated recovery of circulating platelets and red blood cells and the chronic IL-11 exposure results in the loss of body fat, thymus atrophy and alterations in plasma protein levels

(f) Primates myelosuppressed by carboplatin

IL-11 treatment following chemotherapy significantly improves platelet nadirs and accelerates platelet recovery.

NON-HEMATOPOIETIC EFFECT**1. Gastrointestinal damage***(a) Mice myelosuppressed by 5-FU and radiation*

IL-11 decreases morbidity and mortality caused by endogenous infection from gut organisms; stimulates the proliferation of small intestine crypt progenitor cells and induces recovery of small intestine villus structure; results in a mild increase in peripheral platelet counts.

(b) Hamsters with oral mucositis resulting from 5-FU treatment
IL-11 decreases the frequency, severity and duration of mucositis in a dose-dependent manner and increases animal survival.

2. Inflammatory bowel diseases*(a) HLA-B27 transgenic Fisher 344 rats*

IL-11 decreases the clinical signs and histologic lesion scores of inflammatory bowel disease in these rats.

(b) Acetic acid induced colitis in rats

IL-11 increase platelet counts and decreases the severity of acetic acid-induced colonic injury.

(c) TNBS (trinitrobenzene sulfonic acid) induced colitis in rats

IL-11 decreases the inflammatory lesions in acute colitis induced by TNBS.

3. Systemic inflammatory conditions*(a) Radiation induced thoracic injury in mice*

IL-11 reduces the levels of radiation induced TNF α mRNA in the lung which has been implicated in acute lung injury and interstitial lung disorders.

(b) Toxic shock in mice given D-galactosamine and Staphylococcus aureus enterotoxin B

IL-11 increases survival of these animals.

(c) Pseudomonas sepsis in rats

IL-11 reduces the level of lung infection, pulmonary edema and injury to gastrointestinal epithelium.

(d) Antibiotic-treated newborn rats during experimental group B streptococcal sepsis

IL-11 enhances platelet recovery as well as survival rate of these animals.

(e) Endotoxemia in rats

IL-11 lowers serum levels of inflammatory cytokines such as TNF α , IFN α and IL-1B.

(f) Endotoxemia in rabbits

IL-11 reduces serum levels of proinflammatory cytokines and prevents the hypotension that occurs as a consequence to endotoxemia and is associated with decreased plasma nitric oxide levels.

chemotherapeutic agents will be necessary to evaluate the efficacy of IL-11 in various clinical settings.

INTERLEUKIN 12 AND ITS RECEPTOR

Erwin Rüde, Edgar Schmitt and Tieno Germann, Institut für Immunologie, Johannes-Gutenberg Universität, Mainz, Germany

IL-12 was discovered between 1986 and 1990 independently by four groups by its costimulatory activity for T and natural killer (NK) cells. This is illustrated by the original functional designations of CLMF (cytotoxic lymphocyte maturation factor, M.

Gately *et al*) and NKSF (natural killer cell stimulatory factor, G. Trinchieri *et al*) for human interleukin 12 (IL-12) as well as TSF (T cell stimulating factor, T. Germann, E. Rüde) and IL-2RIF (IL-2 receptor inducing factor, H. Nariuchi *et al*) for murine IL-12.

Whereas TSF and IL-2RIF were obtained from normal splenic accessory cells or bone marrow-derived macrophages upon interaction with activated T_{H1} cells, NKSF and CLMF were both secreted by Epstein-Barr virus (EBV)-transformed human B cell lines activated by phorbol ester. The human factors could be produced and purified in amounts sufficient for N-terminal sequence analysis. It became apparent that NKSF and CLMF comprised two polypeptide chains, IL-12p40 and IL-12p35. Cloning of both proved the identity of CLMF and NKSF. The designation IL-12 was agreed upon. The mouse IL-12 chains were then cloned by cross-hybridization to the human cDNA probes.

Structure of IL-12 and its receptor (IL-12R)

Structural characteristics of IL-12 and its receptor are summarized in Table 1. The homologies to other cytokines, mainly to IL-6 and its receptor, suggest that IL-12 has evolved from a primordial cytokine and its soluble receptor. On activated T cells (human and mouse) IL-12 binding sites of high (K_d 5–50 pM), intermediate (K_d 50–200 pM) and low (K_d 2–6 nM) affinities have been identified. In bioassays IL-12 (mouse and human) is active at concentrations of about 0.1 pM. This indicates that signaling can be induced even at low receptor occupancy. Similarly, a cell line cotransfected with the two cloned hIL-12R β_1 and β_2 chains exhibited binding sites of K_d 50 pM and K_d 5–10 nM and was responsive to IL-12 at 1 pM. Signal transduction induced by IL-12 in T cells was found to include activation of tyrosine kinases JAK2 and TYK2 and phosphorylation of STAT1 (mouse), STAT3 and STAT4 (mouse and human).

Competitive inhibition of IL-12 function by murine IL-12(p40) $_2$

The p40 chain of IL-12 (human and mouse), when synthesized in the absence of p35 (e.g. in cells transfected with p40 cDNA) or when produced in excess over p35, can be secreted as a monomer, IL-12p40, and as a disulfide linked homodimer, IL-12(p40) $_2$. Murine IL-12(p40) $_2$ because of its high affinity binding to the murine IL-12R (Table 1) is an efficient inhibitor of IL-12 activities both *in vitro* and *in vivo*. Synergistic inhibition was observed in combination with certain IL-12-specific antibodies. There are indications that murine IL-12(p40) $_2$ may be synthesized as a physiological inhibitor of IL-12. Human IL-12(p40) $_2$ is a much poorer competitor for human IL-12 (Table 1); possibly it could be used in combination with suitable antibodies for more efficient inhibition of IL-12 functions.

Production of IL-12 and its regulation

Although human IL-12 was originally discovered in the supernatants of transformed human B cell lines, normal B cells (human or mouse) were not found to synthesize significant amounts of IL-12 (murine B cells stimulated by bacterial DNA may be an exception). The main producers of IL-12 belong to the macrophage/dendritic cell (DC) lineage. It is important to note that the capacity of macrophages to synthesize IL-12 depends on their functional stage (Table 2). Neutrophils, upon stimulation by lipopolysaccharide (LPS), were also found to produce IL-12, although less efficiently than monocytes. Furthermore, Langerhans cells, microglia cells, astrocytes, connective tissue type mast cells and keratinocytes could be identified as IL-12 producers.

Regulation of IL-12 synthesis is complex because it is controlled by two independent genes which have to be coexpressed in the same cell. There are indications that mRNA expression for the two chains does not always correlate. The p40 chain is generally produced in excess over the IL-12 heterodimer. The ratio of p40 to IL-12 can vary from 5:1 to 100:1, depending on the cell type and the stimulus. This may not be trivial because in the case of murine macrophages the IL-12 antagonist, IL-12(p40) $_2$, could be detected among the excess p40 produced. It is obvious that this complicates the determination of IL-12 considerably (see below).

The stimuli leading to IL-12 production have been mainly studied with macrophages/DCs (Figure 1). With respect to the function of IL-12 as a mediator of innate resistance and a link to specific immunity, it is essential that this cytokine (together with other cytokines such as tumor necrosis factor α (TNF α), IL-1, etc.) is produced upon infection/interaction of macrophages with gram-negative as well as gram-positive bacteria on their products (e.g. LPS and others). Furthermore, infection with certain parasites and viruses can induce IL-12 synthesis. A second pathway leading to IL-12 production in macrophages/DCs is initiated by ligation of CD40, which occurs under physiological conditions by interaction with activated, CD40L-expressing T cells of the T_{H1} subtype. No IL-12 is produced upon interaction of macrophages/DCs with T_{H2} cells. This is probably due to the release of IL-10 which inhibits IL-12 production (see below). This pathway of IL-12 production is important to maintain and perhaps further expand an already existing T_{H1} -type response.

Some of the modulators of IL-12 production and their effects are listed in Table 2. It should be noted that IL-10 and transforming growth factor β (TGF β) not only inhibit IL-12 synthesis but also its biological

Table 1 Some structural characteristics of IL-12 and its receptor*Interleukin 12 (IL-12)*

Human (h) and murine (m) IL-12 are both 70–75 kDa proteins composed of two polypeptide chains, IL-12p40 and IL-12p35, linked by one disulfide bridge. Murine IL-12 can function on human cells but human IL-12 does not function on mouse cells

hIL-12p40:	~40 kDa, 306 amino acids calculated mol. wt 34 699, 10 Cys: 8 in intrachain disulfide linkages. 1 Cys forms a bridge to IL-12p35, 1 Cys modified by thioglycolic acid or by cysteine, 4 potential <i>N</i> -glycosylation sites, 10% carbohydrate Amino acid sequence shows homology to IL-6R α chain Encoded on chromosome 5q31–q33
hIL-12p35:	~35 kDa, 197 amino acids, calculated mol. wt 22 500, 7 Cys: 6 in intrachain disulfide linkages, 1 Cys forms bridge to IL-12p40, 3 potential <i>N</i> -glycosylation sites, 20% carbohydrate Amino acid sequence shows homology to IL-6 and G-CSF Encoded on chromosome 3p12–q13.2
mIL-12-p40:	~40 kDa, 70% cDNA sequence and 70% amino acids sequence identity with hIL-12p40 Encoded on chromosome 11
mIL-12p35:	~35 kDa, 67% cDNA sequence, 60% amino acids sequence identity with hIL-12p35 Encoded on chromosome 6(3)

Interleukin 12 receptor (IL-12R)

Two receptor chains IL-12R β_1 and IL-12R β_2 have been identified and cloned

hIL-12R β_1 :	~100 kDa, type I membrane protein, 638 amino acids calculated mol. wt 70 400, extracellular portion 516 amino acids, transmembrane region 31 amino acids, intracellular portion 91 amino acids.
hIL-12R β_2 :	~130 kDa, type I membrane protein, 835 amino acids, calculated mol. wt 94 059, extracellular portion 595 amino acids, transmembrane portion 24 amino acids, intracellular portion 216 amino acids Both β_1 and β_2 chains are members of the cytokine receptor superfamily and are related to gp130 of the IL-6R and to receptors of LIF and G-CSF. Coexpression of IL-12R β_1 and β_2 confers IL-12 responsiveness and results in binding sites of K_d 50 pM and of K_d 5–10 nM; expression of either chain alone results in binding sites of K_d 2 to >50 nM.
mIL-12R β_1 :	54% amino acid sequence identity with hIL-12R β_1 The cDNA of mIL-12R β_1 was reported to occur in 3 additional splice variants (β_{1a} , β_{1b} and β_{1c})
mIL-12R β_2 :	68% amino acid sequence identity with hIL-12R β_2
h + mIL-12R:	Expressed on 'resting' NK cells but not on resting T and B cells. Upregulation upon activation on T cells and NK cells. Expression on activated B cells is not yet firmly established

IL-12 (pP40) $_2$: a competitive inhibitor of IL-12

IL-12(p40) $_2$ is a disulfide-linked homodimer that can be secreted in addition to the IL-12p40 monomer by cells producing IL-12p40

hIL-12(p40) $_2$:	Binds to the high affinity hIL-12R with 5- to 10-fold lower affinity than hIL-12 and is therefore not a potent inhibitor of hIL-12
mIL-12(p40) $_2$:	Binds to the high affinity mIL-12R with similar affinity as mIL-12 itself but without stimulation of the cells. mIL-12(p40) $_2$ is therefore a potent competitive inhibitor of mIL-12
mIL-12p40: (monomer)	Binds with 25- to 50-fold lower affinity to the IL-12R than mIL-12(p40) $_2$

activities on T cells. Furthermore, the role of CD46, which is a receptor for measles virus and a binding protein for C3b/C4b, is remarkable because it selectively inhibits the synthesis of IL-12 but not that of TNF α and IL-6 by macrophages.

Cells responsive to IL-12

The major cell types that respond to IL-12 are NK cells and T cells, the latter including CD4 $^+$ and CD8 $^+$ T cells as well as $\gamma\delta$ T cells (Figure 1). Furthermore, hematopoietic precursor cells were found to respond

to IL-12 *in vitro* with increased proliferation and differentiation, whereas application of IL-12 *in vivo* leads to anemia, neutropenia and lymphopenia due to indirect effects of interferon γ (IFN γ) induced by IL-12. IL-12 has also been reported to act on activated B cells to increase immunoglobulin (Ig) secretion. Recently, murine B cells activated by crosslinking of CD40 were found to produce relatively high concentrations of IFN γ in response to a combination of IL-12 and IL-18 and this cytokine combination led to a shift in the production of IgG $_1$ /IgE to IgG $_{2a}$. The main effects of IL-12 on NK

Figure 1 Stimuli that induce IL-12 production in macrophages/dendritic cells (DCs) and some of the biological effects of IL-12 on NK and T cells.

Table 2 Modulators of IL-12 production^a

Positive modulators

IFN γ :	Preincubation of macrophages or neutrophils
GM-CSF:	Preincubation of macrophages (DCs are generally cultivated with GM-CSF)
IL-4, IL-13:	Monocytes (human); depending on conditions the synthesis of IL-12 can also be inhibited (see below)

Negative modulators

IL-10:	Potent inhibitor for macrophages and DCs, also inhibits synthesis of other cytokines (e.g. TNF α , etc.)
TGF β :	Strong inhibitor, also for other cytokines (e.g. TNF α , etc.)
IL-4, IL-13:	Partial inhibition in monocytes (human) (see above)
Prostaglandin E ₂ :	Leads to elevation of cAMP, inhibition of IL-12 and TNF α production
Phosphodiesterase inhibitor:	Leads to elevation of cAMP, inhibition of IL-12 and TNF α production
CD46 cross-linking	Induced by measles virus, dimerized C3b or antibodies to CD46 Selective inhibition of IL-12 but not of TNF α or IL-6 synthesis in human macrophages

^aThe results summarized in this table were mainly obtained with monocytes/macrophages as the IL-12-producing cells.

and T cells are the enhancement of cytokine production, costimulation of proliferation, and the enhancement of cytotoxic activity. Possibly most important is the induction of IFN γ synthesis at different levels. In addition, the production of TNF α , granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-2 by T cells is promoted. The importance of IL-12 for optimal IFN γ production in the course of immune responses *in vivo* was demonstrated by the use of mice with targeted disruption of the IL-12p40 or p35 genes.

Innate resistance to infections is mediated by IL-12 that synergizes with IL-1 β and/or TNF α in inducing IFN γ production by NK cells. This proinflammatory effect of IL-12 which via IFN γ leads to activation of macrophages can not only mediate protection but also pathological septic shock-like effects. The fact that IL-12 is a potent costimulator for T cells constitutes an important link between innate and acquired immunity (Figure 1).

IL-12 synergizes with T cell receptor (TCR)-stimu-

lation and with other costimuli (IL-2, CD28-ligation) in inducing IFN γ production by T cells. Another important aspect of IL-12 function is the induction of differentiation of naive CD4⁺ T helper cells to T_H1 cells. These are characterized by their high capacity to produce IFN γ . Furthermore, IL-12 functions as a costimulator that synergizes with signaling via CD28 inducing IFN γ production and proliferation of T_H1 cells. Thus, IL-12 is generally known as the major inducer of T_H1-type immune responses *in vitro* and *in vivo*. However, one should notice that in the presence of small amounts of IL-4, which by itself will lead to T_H2 development of naive T_H cells, the addition of IL-12 does not suppress but rather enhances this T_H2 development. Such effects of IL-12 have been also observed *in vivo*. Injection of IL-12 into mice led to expression of IL-10 (in addition to IFN γ) in not yet identified cell types. It was shown that *in vitro* priming of human T cells in the presence of IL-12 not only resulted in the development of cells producing IFN γ but also IL-10. This would represent a feedback mech-

anism since IL-10 can inhibit further IL-12 synthesis by macrophages and IL-12R expression on T cells (see below).

Regulation of responsiveness to IL-12

Responsiveness of T cells to IL-12 is controlled by IL-12R expression. Resting T cells do not express the receptor, which is transiently upregulated relatively late (day 3–4) after activation of T cells (Table 1). In addition to this basic regulation, the responsiveness of activated IL-12R expressing human T cells is strongly enhanced by interaction of CD2 with CD58 on accessory cells. No such effect has yet been observed with mouse T cells. Negative regulation of IL-12 responsiveness occurs in naive T_H cells developing toward T_H2 cells under the influence of IL-4. This loss of IL-12 reactivity is due to the downregulation of IL-12R β_2 and is counteracted by the presence of IFN γ . An important modulator that strongly inhibits the effects of IL-12 is TGF β . Indeed it was reported that TGF β and IL-10 strongly inhibit upregulation of IL-12R β_2 , and moderately inhibit upregulation of IL-12R β_1 , on human T cells.

Immune modulation by IL-12

The importance of early IL-12 production for stimulation of innate immunity and the development of protective T_H1 -type immune responses in infectious disease models has already been mentioned. Resistance to a malaria infection could be achieved by a prophylactic treatment of monkeys or mice with IL-12. In cases of an insufficient T_H1 response (e.g. *Leishmania* infection of susceptible BALB/c mice) the early administration of IL-12 could correct this defect. However, an already established disease-promoting T_H2 response could not be reverted.

IL-12 could be detected in the early phases of some but not all virus infections and was found to assist in the development of immunity. While administration of IL-12 depending on its dosage had beneficial effects with some virus infections it led to toxic, septic shock-like effects in others (e.g. lymphocytic choriomeningitis virus; LCMV). Since macrophages of patients with the acquired immune deficiency syndrome (AIDS) are deficient in producing IL-12, and addition of IL-12 to peripheral blood mononuclear cells (PBMC) of AIDS patients restored antigen-induced IFN γ production and proliferation of T cells, treatment with IL-12 *in vivo* in analogy to the mouse model of MAIDS might contribute to restoration of cellular immune functions.

When administered together with protein antigens, IL-12 showed a strong adjuvant effect. It promoted the development of T_H1 -type responses and, after a moder-

ate reduction of early IgG1 production, it led to weakly enhanced late IgG1 and strongly enhanced IgG2a, IgG2b and IgG3 responses. An established IgE response could not be permanently suppressed. Under certain conditions, the induction of an IgE response was even enhanced. This adjuvant effect of IL-12 has been successfully employed to immunize mice with defined bacterial protein antigens. While poor *in vivo* protection was achieved with Al(OH) $_3$ as adjuvant, IL-12 supported the development of protective immunity comparable to whole bacterial vaccines. The involvement of endogenously produced IL-12 was also demonstrated for the induction of contact sensitivity that represents a classical T_H1 -type response. When administered together with a contact allergen, IL-12 also functioned as an adjuvant.

T_H1 -type responses to autoantigens are considered to be characteristic for several organ-specific autoimmune diseases. It could be demonstrated that in certain mouse models of antigen-induced or spontaneous autoimmune diseases administration of IL-12 can accelerate the development of disease. But IL-12 could also inhibit or delay disease development if higher doses or a different application regimen were employed. Furthermore, in some of the models IL-12-specific antibodies, when applied therapeutically, led to a reduced incidence and severity of the disease.

Finally, IL-12 has been extensively tested as an adjuvant for inducing tumor specific immunity or as a therapeutic agent against established tumors in a variety of mouse models. Protective immunity could be induced upon preimmunization in some models and striking inhibitory effects on tumor growth and metastasis formation were observed in others. In some models CD8 $^+$ T cells were found to be required, yet generally the underlying mechanisms appear to be complex.

Determination of IL-12

The determination of IL-12 can be carried out by biological assays or by ELISA. Biological assays for IL-12 are very sensitive and are mostly based on the 'capture' technique. The assay wells are precoated with an antibody against IL-12 that should be specific for the heterodimer, but not neutralizing and not binding to IL-12p40 or IL-12(p40) $_2$. After capturing IL-12 the responding cells (e.g. activated T cells) are added and the resulting IFN γ production or proliferation can be measured. This avoids, especially in the mouse system, inhibitory effects of IL-12(p40) $_2$, which may be also present in the test fluids. A sandwich ELISA uses the same primary antibody to bind IL-12 but not the p40 chain that is usually produced in excess over IL-12. A

secondary anti-IL-12p40 or anti-IL-12p35 antibody can then be used for detection of the IL-12 bound.

Interleukin 13 (IL-13) has biological activities on B cells, monocytes/macrophages and endothelial cells. IL-13 is primarily produced by T_H2 cells, but it is also secreted by other T helper cell subsets $CD8^+$ T cells, mast cells, eosinophils and basophils following activation. IL-13 induces proliferation and immunoglobulin E (IgE) synthesis by human B cells, suggesting that it may play a role in the pathogenesis of IgE-mediated allergic diseases. Moreover, IL-13 inhibits production of proinflammatory cytokines and chemokines by monocytes/macrophages both *in vitro* and *in vivo*, indicating that IL-13 also has important anti-inflammatory properties.

Molecular characteristics of IL-13

Human IL-13 is a 12 kDa nonglycosylated four-helix, α -helical protein. Alternative splicing results in two functionally similar isoforms of hIL-13 consisting of 131 or 132 amino acids, the latter having an additional glutamine residue at position 98. IL-13 protein is approximately 25% homologous to IL-4, and all residues that contribute to the hydrophobic structural core of IL-4 are conserved, or have conservative replacements in IL-13, suggesting that the three-dimensional structures of IL-4 and IL-13 are comparable. The gene encoding human IL-13 is located on chromosome 5q31, in the same cluster of genes encoding the cytokines IL-3, IL-4, IL-5, IL-9 and granulocyte-macrophage colony-stimulating factor (GM-CSF). The IL-13 gene is only 12 kb upstream from the gene encoding IL-4, indicative for gene duplication during the evolution of these two genes. IL-13 and IL-4 share many, but not all, biological properties, which is partially due to differential expression of IL-4 and IL-13 receptors.

IL-13R complex

The high-affinity IL-13 receptor complex comprises the IL-4R α chain and an IL-13 binding protein, termed the IL-13R α chain. The IL-13R α chain is a ~70 kDa glycosylated molecule, which is homologous with the IL-5R α chain (51% similarity and 27% identity). The IL-13 receptor is expressed on B cells, monocytes/macrophages, basophils, mast cells and endothelial cells, but not on T cells. The IL-13R complex also functions as a second receptor for

IL-4, whereas the other IL-4R complex, consisting of the IL-4R α chain and the common γ chain, is specific for IL-4 (Figure 1). The IL-4R α chain alone binds IL-4 with a relatively high affinity ($K_d \sim 10^{-10}M$), whereas the IL-13R α chain is a specific binding protein for IL-13 ($K_d 2.5 \times 10^{-10}M$).

Data obtained with cells from patients with X-linked severe combined immunodeficiency (SCID) indicate that IL-4 can signal through both IL-13R and IL-4R complexes. SCID patients have mutations in the gene encoding the common γ chain, a shared component of receptors for IL-2, IL-4, IL-7, IL-9 and IL-15. Therefore, their T cells are unable to respond to these cytokines, causing severe abnormalities in both T and B cell functions. However, B cells derived from SCID patients proliferate and produce IgE fol-

Figure 1 IL-13 receptor and IL-4 receptor complex.

lowing stimulation through CD40 in the presence of IL-4 or IL-13, whereas IL-2 and IL-15 were ineffective, demonstrating that both IL-4 and IL-13 can mediate their biological effects through the IL-13R complex in the absence of a functional common γ chain. Binding of IL-13 to the IL-13R α chain, leads to its dimerization with the IL-4R α chain and initiation of the signal transduction cascade.

Stable expression of the murine IL-13R α chain in CTLL-2 cells, which normally respond to IL-4 but not to IL-13, results in the generation of a high-affinity IL-13 binding complex, which transduces a proliferative signal in response to IL-13.

Effects of IL-13 on B lymphocytes

IL-13 induces IgG4 and IgE synthesis by human B cells cultured in the presence of activated CD4⁺ T cells, anti-CD40 monoclonal antibodies (mAbs) or CD40 ligand (L) transfectants. In contrast to human B cells, IL-13 does not induce IgE by mouse B cells under conditions that induce IgE switching in response to IL-4, suggesting that mouse B cells lack functional IL-13R complexes. However, IL-4-deficient mice produce low levels of IgE *in vivo*, following viral or parasite infections, indicating that IL-4-independent IgE synthesis occurs in these mice. However, it is not known whether this IgE production is mediated by IL-13.

The effects of IL-13 on human B cells are largely similar to those of IL-4, but IL-13 is generally less potent than IL-4 in inducing IgE synthesis.

IL-13 modulates the phenotype of normal human B cells. It upregulates the expression of CD23, CD71, CD72, surface IgM (sIgM) and major histocompatibility complex (MHC) class II molecules on purified human B cells. IL-13 has growth-promoting activity on normal B cells stimulated by anti-IgM or anti-CD40 mAbs, but it inhibits IL-2-induced proliferation of chronic lymphocytic leukemia B cells, suggesting that IL-13 has antiproliferative effects on malignant B cells.

IL-13 does not have additive or synergistic effects with IL-4 when both cytokines are added at optimal concentrations, which is consistent with the observation that the receptors for IL-4 and IL-13 share a common component, which is important for signal transduction.

Role of IL-13 in atopic diseases

Although both IL-4 and IL-13 induce IgE synthesis by human B cells *in vitro*, the relative contribution of the two cytokines to IgE synthesis under physiological situations remains to be determined. This is largely due to lack of suitable animal models.

Several lines of indirect evidence suggest that both IL-4 and IL-13 are required for optimal induction of human IgE synthesis. Both IL-4 and IL-13 are upregulated in the lungs of asthmatic patients after allergen challenge, indicating that both cytokines play a role in the regulation of allergic inflammatory responses. Atopy has been linked to genes in chromosome 5q31.1 in the area where the genes encoding IL-4 and IL-13 are located, suggesting a genetic predisposition for enhanced IL-4 and IL-13 production in atopic individuals. However, neutralization of either IL-4 or IL-13 activities in supernatants of activated allergen-specific T_H2 cells with anti-IL-4 or anti-IL-13 mAbs indicated that IL-4 is the dominant cytokine in inducing IgE synthesis. On the other hand, the fact that IL-13 is also produced by naive T cells and T cell subsets not producing IL-4 suggests that IL-13 may be the dominant cytokine inducing IgE synthesis in situations where IL-4 is absent or present at low levels, e.g. during the initiation of allergic responses.

Effects of IL-13 on monocytes and endothelial cells

The effects of IL-13 on monocytes/macrophages and endothelial cells are similar to those of IL-4. IL-13 modulates the phenotype of both human and murine monocytes/macrophages and it inhibits production of proinflammatory cytokines, chemokines and nitric oxide by these cells. IL-13 inhibits synthesis of IL-1 α , IL-1 β , IL-6, IL-12, tumor necrosis factor α (TNF- α) and the chemokines IL-8, macrophage inflammatory protein (MIP-1 α) and MIP-1 β by monocytes. In addition, it enhances production of the IL-1 receptor antagonist, which is a secreted protein with anti-inflammatory properties. IL-13 also inhibits IL-1 β and TNF α production by synovial fluid macrophages from patients with rheumatoid arthritis, suggesting that IL-13 may have therapeutic potential in the treatment of inflammatory arthritis. This notion is supported by the observation that IL-13-producing cells attenuate collagen-induced arthritis in mice. IL-13 was also shown to suppress experimental autoimmune encephalomyelitis in rats, further demonstrating its anti-inflammatory properties *in vivo*. In addition, IL-13 enhances expression of CD11b, CD11c, CD18, CD23 and MHC class II molecules, whereas it decreases expression of CD14, CD16, CD32 and CD64 on monocytes and macrophages.

IL-13 induces VCAM-1 expression on human umbilical vein endothelial cells, which results in adhesion of eosinophils to these cells. Eosinophils accumulate at sites of allergic inflammation, and they are thought to play a crucial role in the pathogenesis

of the lung inflammation and in lung epithelial cell destruction in asthmatic patients. Consequently, the ability of IL-13, like that of IL-4, to induce VCAM-1 expression on endothelial cells further emphasizes the importance of these cytokines in the pathogenesis of allergic and asthmatic responses.

Comparison of the functional properties of IL-4 and IL-13

Despite the structural and functional similarities between IL-4 and IL-13, there are also important differences (Table 1), which implies that IL-4 and IL-13 are likely to have distinct roles in the regulation of immune responses *in vivo*.

In contrast to IL-4, IL-13 does not have growth-promoting effects on activated human peripheral blood CD4⁺ or CD8⁺ T cells or T cell clones, and does not direct T_H2 cell differentiation. However, IL-13 may indirectly affect T cell functions and T cell differentiation through its downregulatory effects on the production of IL-12 and interferon α (IFN α), which direct T_H1 development. These differential effects of IL-4 and IL-13 on activated T cells appear to be due to absence of high affinity IL-13R complexes on these cells.

In addition to T cells, B cell precursors differ in their responses to IL-4 and IL-13. Both IL-4 and IL-13 induce proliferation and differentiation of immature CD19⁺, s μ ⁺ fetal B cells, but in contrast to

IL-4, IL-13 does not induce CD23, CD40 or HLA-DR expression or germline ϵ RNA synthesis in CD19⁺, s μ ⁺ human pre-B cells. These distinct effects of IL-4 and IL-13 on pre-B cells suggest that functional IL-13R is expressed at a later stage of B cell ontogeny than IL-4R and that IL-13, in contrast to IL-4, does not regulate early B cell maturation.

The different roles of IL-4 and IL-13 in the regulation of inflammatory responses *in vivo* are not only determined because they act on partially different target cells but also because both cytokines can be produced by different cells. IL-13 is not only produced by T_H2 cells, but also by T_H0 cells, and in contrast to IL-4 by naive CD45RA⁺ T cells and T_H1 cells. However, all T cells that produce IL-4 produce IL-13 when studied at the single cell level. The kinetics of IL-13 production by activated T cells also differs significantly from that of IL-4. IL-4 mRNA appears 2–4 hours after activation, and it is almost undetectable after 12 hours, whereas IL-13 mRNA can still be observed 48 hours after T cell activation, suggesting that IL-13 is produced for significantly longer time periods after antigen-specific T cell activation.

There are also similarities in IL-4 and IL-13R signal transduction pathways. Both IL-4 and IL-13 induce phosphorylation of STAT6 (STAT = signal transducer and activator of transcription), which is also necessary for the biological activities of both cytokines. STAT6-deficient mice are unable to produce IgE and their T_H2 cell differentiation is impaired. However IL-4, but not IL-13, induces phosphorylation of JAK3, which is probably due to the fact that JAK3 associates with the common γ chain, which is not an essential component of IL-13R complex.

INTERLEUKIN 15 AND ITS RECEPTOR

Mary K Kennedy and Linda S Park, Immunex Corporation, Seattle, Washington, USA

Interleukin 15 (IL-15) is a cytokine that shares many *in vitro* activities with IL-2. The IL-2-like activity of this cytokine was initially described by two groups. The activity detected in concentrated supernatants of a monkey kidney epithelial cell line was molecularly cloned and given the name IL-15, whereas the activity in supernatants from a human T lymphotropic virus type I (HTLV-I)-transformed, human adult T cell leukemia line was designated IL-T. The IL-T protein has recently been shown to be identical to human IL-15.

The shared activities of IL-15 and IL-2 stem from their use of common receptor subunits. IL-15 interacts with a receptor complex that consists of both the β and γ_c chains of the IL-2R as well as a specific, high-affinity IL-15-binding subunit, designated IL-15R α . Although IL-2 and IL-15 have overlapping activities on cells of the immune system, the differential expression of these cytokines within tissues and by various cell types suggests that these cytokines perform some distinct physiological functions. The production of IL-15 by macrophages and other cell types in response to environmental stimuli and infec-

tious agents suggests that IL-15 plays a role in protective immune responses and immune disorders.

Expression of IL-15 mRNA and protein

In contrast to the expression of IL-2 mRNA, which is limited to activated T cells and to tissues that contain T cells, IL-15 mRNA is not expressed by activated normal T cells but is expressed constitutively (but often at low levels) in a wide variety of cell types and in many different tissues (Table 1). There is no evidence that normal human or mouse T or B cells express IL-15 mRNA. The predominant IL-15 message produced by the HTLV-I transformed human T cell line HuT-102 is smaller than that produced by nontransformed human cells and represents a chimeric mRNA that joins a segment of the HTLV-I long terminal repeat with the open reading frame of IL-15.

The expression of IL-15 mRNA by macrophages is enhanced in response to microbial products (Table 1). Although IL-15 mRNA expression is easily detected in lipopolysaccharide (LPS)-stimulated

Table 1 Characteristics of IL-15

Chromosomal location	4q31 (human); central region of 8 (mouse)
Polypeptide length	Mature protein: 114 amino acids; signal sequence: 48 amino acids
Predicted disulfide bonds	Cys35-Cys85, Cys42-Cys88, conserved in simian, human and mouse
Carbohydrate	Potential <i>N</i> -linked sites: Asn71, Asn79, Asn112 (human); Asn56, Asn60, Asn71, Asn112 (mouse)
Sequence homology of full-length proteins	Human and simian IL-15: 96% amino acid identity human and mouse IL-15: 73% amino acid identity
Heterotrimeric receptor complex	IL-15R α /IL-2R β / γ_c
Cellular sources of IL-15 mRNA	Monocytes/macrophages, epithelial cells, endothelial cells, fibroblasts, keratinocytes
Stimuli that increase IL-15 expression	IFN γ , LPS, infectious agents, UVB radiation
Biological effects of IL-15	Growth factor for activated T, B, and NK cells; chemoattractant and chemokinetic factor for T cells; induces cytotoxic activity and cytokine production by NK and T cells (synergizes with IL-12)

monocytes/macrophages, it has been difficult to detect IL-15 in unconcentrated supernatants from such cells. It has been suggested that this disparity is due in part to 10 upstream AUGs in the 5' untranslated region of IL-15 mRNA, which act to attenuate translation. However, recent studies have shown that IL-15 is produced *in vitro* as well as *in vivo*. For example, IL-15 is secreted by human keratinocytes upon exposure to UVB radiation. In addition, human peripheral blood mononuclear cells (PBMCs) or monocytes and mouse macrophages produce IL-15 in response to bacterial products, such as LPS, or in response to bacterial or viral infection. The optimal production of IL-15 by mouse macrophages has been shown to require both priming (by interferon γ , IFN γ) and triggering (by bacterial products).

The IL-15R complex

IL-15 interacts with a heterotrimeric receptor that contains both the β and the γ_c chains of the IL-2R as well as a unique IL-15-binding subunit. This subunit has been designated IL-15 α (Table 2) by analogy

Table 3 IL-15 binding affinities and proliferative response of cells expressing various forms of the IL-15R

Receptor subunits	$K_a(m^{-1})^a$	Response to IL-15 ^b
IL-15R α^c	10^{11}	—
IL-15R $\alpha\beta^{c,d}$	10^{11}	—
IL-15R $\alpha\beta\gamma^{c,d,e}$	10^{11}	+++
IL-15R $\alpha\Delta\text{cyt}\beta\gamma^{d,e,f}$	10^{11}	+++
human $\beta\gamma$	10^9	+
mouse $\beta\gamma$	Not detectable	+ ^g
IL-2R α^c	Not detectable	—

^aBinding affinities were determined using ^{125}I -simian IL-15. Limits of accurate determination of binding affinities are between 1×10^7 and $1 \times 10^{11} \text{ m}^{-1}$.

^bMeasured by incorporation of [^3H]thymidine by various cell lines.

^cRefers to either the mouse or human IL-15/IL-2R subunits.

^dThe β chain of the IL-15R is also a component of the IL-2R.

^eThe γ chain of the IL-15R is also a component of the receptors for IL-2, IL-4, IL-7, IL-9.

^fCells were transfected with IL-15R $\alpha\Delta\text{cyt}$, a deletion mutant of mouse IL-15R α that lacks all but five amino acids of the predicted cytoplasmic domain.

^gProliferation was detected in response to high concentrations (500 ng ml^{-1}) of human or simian IL-15. Such cells are 10–100 fold more responsive to mouse IL-15.

Table 2 Characteristics of the IL-15R α chain

Chromosomal location	10, bands p14–p15 (human); proximal region of 2 (mouse)
Polypeptide length	Mouse IL-15R α : mature protein: 231 amino acids; signal peptide: 32 amino acids; extracellular domain: 175 amino acids; cytoplasmic domain: 37 amino acids
Predicted disulfide bonds	Mouse IL-15R α : Cys4-Cys46, Cys30-Cys64
Carbohydrate	Mouse IL-15R α : potential <i>N</i> -linked site at Asn19, many potential sites for <i>O</i> -linked glycosylation
Alternatively spliced forms	Mouse: none detected Human: one is homologous to mouse IL-15R α cDNA, a second has a deleted exon in the extracellular domain, a third has an alternative cytoplasmic domain. No alternatively spliced mRNAs encoding soluble forms of mouse or human IL-15R α have been detected.
Cellular sources of IL-15R α mRNA and cell surface protein	Epithelial and bone marrow stromal cell lines, fibroblasts, T cells, NK cells, B cells, endothelial cells, monocytes/macrophages
Stimuli that increase or decrease IL-15R α expression	Increase: Anti-CD3, PMA (T cells); IFN γ (macrophages) Decrease: IL-15 (human T and B cells)

to the IL-2R α to which it is structurally related. As compared to IL-2R α , IL-15R α has a broader distribution of expression in different cell types and shows a much higher affinity for its ligand in the absence of the IL-2R β and γ_c chains. Whereas IL-2R α exhibits a low affinity ($K_a = 10^8 \text{ M}^{-1}$) for IL-2, IL-15R α binds IL-15 with a high affinity ($K_a = 10^{11} \text{ M}^{-1}$). The expression of IL-15R α can be upregulated in response to various stimuli (Table 2). Interestingly, although both IL-2 and IL-15 upregulate IL-2R α expression on human B and T cells, IL-15 downregulates the expression of IL-15R α on these cells. In addition, although a soluble, shed form of IL-2R α can be detected in biological fluids, it is not known whether a shed form of IL-15R α exists.

In cells of hematopoietic origin, the IL-2R β and γ_c chains are essential for signaling by either IL-2 or IL-15. Similar to what is observed in the IL-2/IL-2R system, the IL-15R α chain is required for high-affinity binding, but not signaling, by IL-15 (Table 3). It is therefore not surprising that the signaling pathways thus far described for IL-2 and IL-15 are identical. However, the IL-2R and IL-15R α chains control a cell's sensitivity to these two cytokines since specific, high-affinity binding of IL-2 or IL-15 requires the presence of the appropriate α chain of the receptor. Human cells that express IL-2R β and γ_c , but not IL-15R α , can bind and respond to human IL-15 *in vitro*, although relatively high concentrations of the cytokine are required to induce a response. Mouse cells expressing IL-2R β and γ_c , but not IL-15R α , are unable to bind IL-15 with a measurable affinity but are responsive to human or mouse IL-15. However, such cells are 10–100 fold more responsive to mouse IL-15. It is not clear whether human or mouse cells expressing IL-2R β and γ_c in the absence of IL-15R α will respond to physiological concentrations of IL-15 *in vivo*.

The significance of cells that express IL-15R α , but lack IL-2R β and/or γ_c , is also not clear. However, such cells would probably bind IL-15 with high affinity but would not be capable of responding to it. These cells might serve either to sequester IL-15 or to create high local concentrations of IL-15 that could be 'presented' to cells capable of responding to it. It is also possible that IL-15R α associates with as yet unidentified receptor subunits to signal in cells that express IL-15R α but lack IL-2R β and/or γ_c .

Biological effects of IL-15

IL-15, like IL-2, is a growth factor for activated mouse and human T cells, activated, purified human B cells, and a subpopulation of human natural killer (NK) cells. In addition, IL-15 synergizes with IL-12

to induce proliferation of resting mouse T_H1 clones and CD4⁺ T cell blasts. IL-15 induces locomotion and migration of human T cells, but appears to have no chemokinetic or chemotactic activity on human monocytes, neutrophils or B cells. IL-15 stimulates cytokine production by NK cells, especially when used in combination with IL-12, and will also induce cytokine production by T cells. Human B cells stimulated with the combination of soluble CD40L and IL-15 secrete polyclonal immunoglobulin M (IgM), IgG1, and IgA, but not IgG4 or IgE.

IL-15 enhances cytotoxic activity of both T cells and NK cells. It induces alloantigen-specific cytotoxic T lymphocytes (CTLs) from human mixed leukocyte cultures and lymphokine-activated killer (LAK) activity from cultures of human PBMCs, large granular lymphocytes, or NK cells. IL-15 treatment induces protective antitumor responses in mouse tumor models that have been shown to be responsive to IL-2 therapy and in which antitumor activity involves either the induction of LAK activity or tumor-specific CTLs.

Potential physiological roles of IL-15

The presence of IL-15 mRNA in many normal tissues and the increased production of IL-15 by macrophages/monocytes in response to bacterial or viral products suggests a role for IL-15 in protective immune responses, allograft rejection, and the pathogenesis of autoimmune diseases. Recently, a possible role for IL-15 in the pathogenesis of rheumatoid arthritis has been suggested. IL-15 is present in the synovial fluid of rheumatoid arthritis patients where it might contribute to recruitment of T cells and provide a means of stimulating T cells to produce macrophage-activating cytokines such as IFN γ , tumor necrosis factor α (TNF α) and granulocyte-macrophage colony-stimulating factor (GM-CSF).

Studies of IL-2 and IL-2R α knockout mice have revealed that IL-2 provides an immunoregulatory role in the immune system that cannot be compensated for by IL-15 or other cytokines. Comparative studies using the IL-2, IL-2R α , and IL-2R β knockout mice are likely to reveal defects in the IL-2R β knockout mice that can be attributed to the lack of both IL-2- and IL-15-mediated responses. The use of IL-15 antagonists *in vivo* and the generation of IL-15 knockout mice will provide further insight regarding the physiological roles of IL-15.

INVARIANT CHAIN (Ii)

Elizabeth K Bikoff, Department of Molecular and Cellular Biology, The Biological Laboratories, Harvard University, Cambridge, Massachusetts, USA

Since its discovery as the third polypeptide chain coprecipitated with polymorphic class II products of the major histocompatibility complex (MHC), molecular immunologists have attempted to understand the physiological significance of the so-called invariant (Ii) chain (CD74) and its possible contributions to the structure and function of MHC-encoded class II membrane glycoproteins. Early observations made in transfection assays suggested that the Ii chain was not required for class II surface expression, but instead played a role during antigen presentation. Recent analysis of mutant mouse strains created using ES cell technology have confirmed the essential nature of Ii chain activities with respect to class II maturation and antigen presen-

tation and also demonstrated its role during thymic selection of the CD4⁺ T cell subset.

Structure

The application of molecular cloning techniques in the mid to late 1980s led to the isolation of Ii chain cDNAs and characterization of the corresponding genomic locus. The Ii chain was found to be encoded by a highly conserved single copy gene unlinked to the MHC, located on human chromosome 5 and mouse chromosome 18. An interesting aspect of the overall structure of Ii chain as shown in **Figure 1**, is that this type II transmembrane protein is oppositely oriented in comparison to MHC class II α and β

Figure 1 The overall structural organization of Ii chain, showing the important functional domains of this type II transmembrane protein.

chains, having its cytoplasmic tail at the N-terminus, followed by the transmembrane domain. The luminal portion of Ii chain responsible for its assembly into oligomeric complexes is located further towards the C-terminus.

Expression

The conserved Ii chain and polymorphic MHC class II molecules are selectively coexpressed in a tissue-specific fashion in conventional antigen-presenting cells such as B cells, macrophages and dendritic cells known to be responsible for initiating CD4⁺ T cell responses. Ii chain and MHC class II gene expression are coordinately upregulated in response to cytokines such as interferon (IFN) and interleukin 4 (IL-4). Many of the transcriptional regulatory elements mapping to their promoter regions appear largely conserved, but control of gene expression differs in at least one important aspect because Ii chain transcripts are far more abundant than MHC class II, probably reflecting in part the

actions of a transcriptional enhancer located in the Ii chain first intron.

Function

The intracellular transport route taken by newly synthesized class II molecules to the cell surface diverges from the constitutive secretory pathway used for class I export. Thus, class II molecules selectively capture antigenic peptides inside endocytic vesicles. The Ii chain contains endosomal targeting signal(s) located near the N-terminus, and has been shown to direct transport of immature class II dimers to peripheral acidic compartments. Selective Ii chain degradation subsequently results in class II peptide occupancy. As far as we know, under physiological conditions the vast majority of mature class II molecules expressed at the cell surface are devoid of Ii chain and are instead tightly occupied by an appropriate peptide ligand.

The Ii chain associates with MHC class II heterodimers to form nine subunit complexes shortly after chain synthesis in the endoplasmic reticulum (ER). As a general rule, assembly of allelically matched $\alpha\beta$ pairs does not require Ii chain coexpression, but in the exceptional case of A α^b A β^b molecules, Ii chain expression has been shown to facilitate production or maintenance of $\alpha\beta$ dimers. In the absence of Ii chain, empty class II molecules tend to aggregate, a property reversed upon occupancy of the peptide-binding site. Thus, the Ii chain serves as the functional equivalent of peptide for class II during early folding of the nascent chains, and protects the otherwise exposed, empty groove from being recognized by ER resident proteins. As for other incompletely or partially assembled oligomeric surface receptors, class II in the absence of Ii chain associates with molecular chaperones such as BiP and calnexin, thought to be responsible for quality control in the ER.

The Ii chain facilitates transport of correctly folded class II $\alpha\beta$ dimers through the Golgi apparatus *en route* to the cell surface. Under physiological conditions, association with Ii chain insures that newly formed $\alpha\beta$ heterodimers are quantitatively exported to endocytic vesicles, thus promoting selective interactions with peptides derived from internalized antigens.

Several closely related Ii chain polypeptides arise from a single Ii chain gene. Comparisons of the Ii chain gene products expressed in humans, mice and rats demonstrate a high degree of evolutionary conservation of structure and function. In humans, the 16 amino acid extension encoded by an alternative in-frame AUG start codon, has been found to contain an ER retention signal. The cytoplasmic domain

of Ii chain contains its endosomal targeting signal(s) including a di-Leu motif thought to be responsible for directing transport to acidic peripheral compartment(s).

The CLIP region

Evidence for class II association with the so-called CLIP region originally came from peptide elution studies. Transfection assays similarly demonstrate this portion of Ii chain is essential for class II chaperone activity. Recent X-ray crystal studies have given us a clear picture of CLIP peptide bound to the human DR3 class II molecule. Interestingly, the overall structure of this ternary complex shows a striking similarity to the class II groove occupied by a conventional antigenic peptide. Thus, CLIP peptide is bound in an extended conformation and has extensive atomic contacts with class II residues contributed by both α and β chains. The CLIP region present on intact Ii chain is part of an unfolded flexible domain and is thus accessible for binding to the MHC class II peptide groove.

CLIP peptide release is mediated by DM, the non-conventional class II product originally described as a facilitator of antigen presentation in mutant human cell lines. CLIP/class II complexes have also been found to accumulate on the surface of mutant mouse spleen cells lacking DM expression. Interestingly, CLIP/class II complexes in these DM mutant mice are not immunogenic and fail to stimulate CD4⁺ T cells. This demonstration of immunological tolerance provides strong evidence that under normal physiological conditions, class II maturation including CLIP removal, is an extremely efficient process.

Other functional domains

Further towards the C-terminus, the highly ordered segment of Ii chain encoded by exons 4–6 comprises a compact α -helical region necessary for trimer formation. There is some evidence that nine subunit complexes are generated via the progressive addition of three $\alpha\beta$ dimers to a core Ii chain trimer. However, experiments analyzing transfected cell lines also suggest that the Ii chain assembles with free α and β subunits.

The cysteine-rich, thyroglobulin-like domain encoded by the alternatively spliced exon 6b represents the most highly conserved portion of Ii chain. Amino acid sequence comparisons between humans, mice and rats show 90% identity. Such a degree of conservation is suggestive of an important function for this region. Two striking features of this portion of Ii chain are especially noteworthy, namely the presence

of two extra conserved sites for attachment of N-linked glycans, and the six luminal cysteines probably involved in disulfide bond formation in the strongly oxidative ER environment. Recent evidence suggests that this domain associates selectively with the lysosomal cysteine protease cathepsin L, and inhibits its activity. On the other hand, numerous experiments seem to suggest a great deal of functional redundancy shared by Ii chain p31 and p41 isoforms. Mutant mouse strains selectively expressing individual Ii chain isoforms exhibit no noticeable differences with respect to class II maturation or antigen presentation to CD4⁺ T cells. Thus the functional significance of this highly conserved region of Ii chain for the most part remains a mystery.

Consequences of invariant chain knockout

The activities of the Ii chain as a specific class II chaperone have been extensively analyzed in transfection assays and mutant mouse strains produced using gene targeting techniques. Under physiological conditions, the loss of Ii chain expression has been shown to cause a dramatic reduction in surface class II expression. As a general rule, mutant spleen cells are defective in their ability to present intact protein antigens, and have greatly reduced numbers of thymic and peripheral CD4⁺ T cells. However, exceptional antigens such as RNAase are presented in association with class II molecules via an Ii chain-independent pathway. Moreover, the extent of Ii chain influence on positive selection of individual CD4⁺ T cells is dependent on their receptor specificities. As yet, only limited information exists concerning the various functional contributions made by Ii chain to CD4⁺ T cell responses *in vivo*. It will be interesting over future years to learn more about the structure and intracellular transport of MHC class II/Ii chain complexes formed in various types of accessory cells such as those responsible for T_H1/T_H2 development, antigen-driven immunoglobulin class switching, somatic diversification, induction of autoimmune diseases, and tissue graft rejection.

INVERTEBRATE IMMUNE SYSTEMS

Christopher J Bayne, Department of Zoology, Oregon State University, Corvallis, Oregon, USA

Gerardo R Vasta, Center of Marine Biotechnology, Baltimore, Maryland, USA

Invertebrates, despite their lack of lymphoid immune systems, recognize and respond to nonself substances at least as efficiently as do vertebrates. Invertebrates rely on a diversity of mechanisms, some of which are inducible; however, the responses are in most cases short-lived and do not discriminate between individual pathogens. Therefore, responses mounted by invertebrates to potentially infectious agents are mediated by immune systems only in the sense that they resemble qualitatively the 'innate' or 'natural' immune responses of vertebrate myeloid cells and nonimmunoglobulin, humoral components. As invertebrates include about 95% of the extant animal species, and represent a vast diversity of organisms, from unicellular protozoans to the more complex echinoderms and protochordates, it is not surprising that a considerable range of strategies for recognition and defense against potential pathogens and parasites are to be found in these taxa.

Through his studies with starfish and water fleas in the nineteenth century, Metchnikoff established comparative immunology. His observation that foreign objects entering the body became covered with white blood cells (leukocytes) led him to consider phagocytosis and encapsulation as fundamental

processes in immune defense. In the 1970s, Hildebrand contributed substantively to the development of a global perspective on the evolution of cellular and humoral immune competence across the spectrum of animal diversity. More recent studies by Boman established the usefulness of invertebrate models for the understanding of antibacterial strategies, some of which have merited conservation throughout the evolution of the chordate lineages.

Invertebrate internal defense responses exhibit common themes such as phagocytosis and encapsulation, but the underlying molecular recognition and effector mechanisms are diverse. Some of the factors involved, such as α_2 -macroglobulins (α_2 -M), C reactive proteins (CRP), antibacterial peptides, serine proteinases and proteinase inhibitors, have been substantially conserved through the evolutionary lineages leading to the chordates, whereas others, such as C-type lectins and complement-related factors, retained only those regions of the molecule that are relevant to recognition/effector functions. Finally, for other factors such as glucan-binding proteins (crustaceans) and some antibacterial peptides, no homologs have been identified in vertebrates so far, and they appear to be restricted to invertebrates. The

potential for finding novel molecules or mechanisms in invertebrates has focused attention on a growing number of species as model organisms, and progress has been substantial during recent years.

Cellular and humoral immune responses

While some leukocytes in protochordate invertebrates (close relatives of the vertebrates) have been termed 'lymphocyte-like cells', evidence that these are homologs of vertebrate lymphocytes remains tenuous: these animals lack the rearranging genes and clonal expansion that characterize the vertebrate lymphoid receptors for antigen.

Among both primitive (acoelomate) taxa, such as the sponges and the corals, and more derived (coelomate, with blood circulatory systems) taxa such as the tunicates (sea squirts, phylum Chordata), many species live permanently fixed to solid substrata where competition for living space is severe, and the risk of being overgrown by neighbors is constant. Here, the ability to preserve one's genome (and pass it on through reproduction) is dependent on aggression toward neighbours. Such responses are effected by cellular and molecular components of the interacting individuals. The kinetics of rejection (establishment of a necrotic zone where contact has occurred) is reduced on second or later encounter. This heightened reactivity is directed specifically at the genotype of the individual that was previously encountered; rejection responses to third party encounters follow kinetics similar to those of first encounters. These responses thus resemble vertebrate graft rejection responses in that they involve leukocyte-mediated alloaggression with specific memory! The fine discrimination of cell surface markers implied by these phenomena is also essential for correct tissue differentiation in all Metazoa. This ability to discern specific markers within a species should not be surprising, since even the earliest free-living eukaryotic amoebae must have been able to distinguish nutritive particles worthy of ingestion (food) from inorganic detritus, and potential mates from potential competitors/aggressors. Mating types, known for modern unicellular eukaryotes (e.g. yeast, *Paramecium*), are identified by means of specific carbohydrate markers (epitopes) on cell surfaces. Also, a diversity of cell surface markers and receptors able to distinguish these is essential for the maintenance of self-sterility and nonself-fertility in plants and animal gametes.

So-called alloaggressive responses occur also in nonsedentary (free-moving), noncolonial invertebrates. Leukocytes from different individual sipunculid worms and echinoderms kill one another on

encounter *in vitro*. And body wall allotransplants made between earthworms, between ribbon worms, between echinoderms, and between solitary tunicates meet fates like those described above for sponges, corals and colonial tunicates. It is surprising to find complex invertebrates in which alloaggression appears to be lacking. This is the case in molluscs (snails) and in insects, where nonself-recognition mechanisms remain poorly understood. Nevertheless, a fascinating variety of effector mechanisms in these animals is responsible for defense against microbial and parasitic infection.

The great variety of blood cells in invertebrates precludes meaningful treatment here. Suffice to say that cells containing respiratory pigments (usually hemoglobin) for the transport of oxygen occur in a small percentage of species. Other pigments, thought not to transport oxygen, occur in echinoderm (sea urchins) granular cells; their functions are unclear. In the majority of taxa, leukocytes (nonpigmented, free cells) are diverse. In primitive species lacking circulatory systems, amoebocytes wander throughout the body, scavenging foreign and damaged material and, in some cases, contributing significantly to the nutrition of the organism. Most invertebrates have not only discrete nervous, excretory and musculoskeletal systems, but circulatory systems as well. In annelids (earthworms and their relatives) and echinoderms, more than one coelomic compartment contains free cells, and the role of scavenger may be met by distinct cell types in distinct locations. Among the more intriguing of the scavenging cells are the motile free cells of sipunculids and the vibratile cells of echinoderms. Common to all taxa, however, are phagocytic cells resembling vertebrate macrophages.

The fate of most foreign particles entering the body of a metazoan invertebrate is to be phagocytosed or, if too large, encapsulated by leukocytes. Fixed phagocytes, analogous to the reticulo-endothelial system, occur in crustacean gills and in the midgut glands of crustaceans and molluscs. All invertebrates, even those lacking body cavities – like sponges, anemones and flatworms – contain phagocytes, and in some species there are more than one phagocytic cell type. Like vertebrate macrophages, these cells orchestrate inflammatory responses, synthesize and use lysosomal enzymes, and possess cytotoxic mechanisms dependent on superoxide and its metabolites.

In addition to phagocytosis, both encapsulation and nodule formation occur in invertebrates. Encapsulation is the net result of frustrated phagocytosis by many leukocytes. Metazoan endoparasites, unless they enter rare susceptible host individuals, elicit encapsulation, often with consequent death to the

invader through toxic intermediates from an enzymatic cascade resulting in melanization. One recognition/effector mechanism, characterized in crustaceans, is the prophenoloxidase activating system that is present in many invertebrates and yields cytokines. A plasma protein binds microbial polysaccharides (LPS or β 1–3 glucans) and induces activation of a prophenoloxidase-activating enzyme that cleaves the proenzyme prophenoloxidase yielding phenoloxidase. This oxidizes phenols to quinones that polymerize and form melanin, all exhibiting antimicrobial properties. Encapsulation may also involve sclerotization, an essential reaction in cuticle development. Nodule formation occurs in insects when large numbers of bacteria enter. In addition to phagocytosis, encapsulation and nodulation, these cells can exhibit cytotoxic responses against foreign pro- and eukaryotic cells.

The interaction of hemocytes with foreign materials can trigger clotting of plasma, limiting the spread of microbes in the body. In horseshoe crabs, hemolymph contains abundant proteins (hemocyanin, limulin/CRP and α_2 -M) and two types of hemocytes. The first – granulocytes – contain two types of secretory cytosolic granules that selectively store proteins participating in defense mechanisms. L-granules contain clotting factors, protease inhibitors (serpins and cystatin), anti-LPS factor and lectins with LPS-binding or bacterial-agglutinating activity. S-granules contain basic proteins with antimicrobial or agglutinating activity. Except coagulogen, all the clotting factors are serine proteases activated by limited proteolysis. LPS from gram-negative bacteria and (1–3)- β -D-glucans from fungi activate factors C and G respectively, triggering the clotting cascade. In synergy with other aforementioned factors, this comprises an effective host defense against pathogens. Hemocytes of the American horseshoe crab (*Limulus polyphemus*) have provided commerce with a sensitive probe for endotoxin.

Recognition molecules

While lacking the rearranging receptor genes of vertebrate lymphocytes, invertebrates do produce members of the immunoglobulin superfamily. In *Drosophila*, these include cell adhesion molecules (fasciclins, neuroglian and lachesin), secreted molecules (amalgam and IMP-L2), receptor-linked protein tyrosine phosphatases (DLAR and DPT), a growth factor (DFGF) and a hybrid protein (peroxidasin). Receptors for tyrosine kinases occur in the sponge *Geodia* and the nematode *Caenorhabditis*. However, within the Ig superfamily, only hemolin, a protein isolated from lepidopterans, can be

induced upon bacterial challenge. A function in non-self recognition has been proposed. Although hemolin exhibits four immunoglobulin-like domains, their primary structure is closer to cell adhesion molecules than to immunoglobulins, and hemolin actually may modulate hemocyte adhesion.

Lectins (carbohydrate-binding proteins) are widespread components of invertebrate fluids and tissues. Commonly multivalent, these molecules, either constitutive or inducible, can aggregate microbes with appropriate saccharide moieties on their surfaces, thereby limiting the spread of potential pathogens. Furthermore, conformational changes of the lectin upon binding to ligand can facilitate phagocytosis. In vertebrates, some calcium-dependent lectins including mannose-binding proteins and the pentraxins CRP and SAP are acute phase proteins, and are involved in innate defenses by way of opsonization and activation of complement. Based on primary structures, *bona fide* homologs of vertebrate pentraxins such as CRP occur in horseshoe crabs, snails and tunicates. The *Limulus polyphemus* CRP is a hexameric structure with a certain degree of polymorphism and not only recognizes carbohydrate structures but also is hemolytic. Together with antibacterial peptides, lysozyme, protease inhibitors and other effector factors, lectins constitute an ancient but efficient defense system. As in vertebrates, lectins in invertebrates function both in recognition and as effector molecules, by direct antibacterial activity or by promoting opsonization/melanization.

Phagocyte surface receptors for nonself are evident when phagocytosis of foreign particles like yeast, bacteria, and erythrocytes occurs in physiological media lacking host molecules – a common observation.

Effector molecules

The most fully understood system of invertebrate defensive molecules is a group of substances synthesized by moths and flies in response to gram-negative or gram-positive bacterial peptidoglycans. In some insects, lysozyme titers also rise in response to this stimulus. Not only have many of these peptides been isolated and sequenced, but their genes and the regulation of their expression have been characterized. Antibacterial peptides are classified into several families: lysozymes, cecropins, sapecins or insect defensins, attacin-like, and proline-rich antibacterial peptides. Some occur even in vertebrates. There may be considerable sequence diversity within each family. Some, such as the cecropins, are targeted broadly and are bactericidal whereas others, such as the attacins, have restricted antibacterial spectra and are

bacteriostatic. Defensive effector molecules must efficiently target putative pathogens without affecting host cells. It appears that, because fatty acids are distributed differently in the prokaryotic and eukaryotic membrane lipid bilayers, antibacterial peptides may selectively target microbial membranes and not those from the invertebrate host. Multiple antibacterial peptides can be synthesized in insect fat bodies and secreted into the blood at relatively high concentrations following immune challenge.

Like some lectins, antimicrobial peptides may have roles in both defense and development. Sapecin, a potent bactericidal peptide from *Sarcophaga*, can be synthesized in larval hemocytes and the fat body in response to body wall injury. However, sapecin is expressed in the embryonic and in the early pupal stages in the absence of exogenous stimuli, and it may be a growth factor for embryonic cells. Some of these defensive molecules have been produced *in vitro* in insect cell, tissue and organ cultures.

The ability to lyse vertebrate erythrocytes (models for more biologically relevant targets), either alone or in combination with cobra venom factor and/or vertebrate serum, occurs in some invertebrate body fluids. Although in some the hemolytic activity is due to phospholipase C-like factors, other lytic factors resemble complement in being heat labile and/or divalent metal ion dependent. In vertebrates, several members of the complement system are mosaic or hybrid molecules constituted by several modules and domains. Complement-related proteins, their modules or domains have been identified in invertebrate species: these include CCP, TSRLDL, C1r/2, EGF, vWF-A, CD5 and the C-type lectin. In echinoderms, there is evidence of a complement-like system which can opsonize erythrocytes for mammalian phagocytes. Echinoderm phagocytes appear to possess complement receptors CR3 and possibly CR1.

Cascades of endogenous serine proteinases (e.g. coagulation and prophenoloxidase activation), important defense responses of invertebrates, require precise modulation in order to avoid damage to host tissues. In vertebrates, complement activation and plasma coagulation are regulated by proteinase inhibitors such as serpins, and equivalent mechanisms are present in invertebrates. Amino acid sequences of invertebrate proteinase inhibitors allow classification into families defined for those from vertebrate origin. For example, α_2 -M, a proteinase inhibitor containing an intrachain thioester bond and structurally related to the vertebrate complement system, has been purified as a 180 kDa dimer in *Limulus*, lobster, crayfish, crab and octopus, and as a tetramer in snails. However, other proteinase inhibitors isolated from some arthropods and one echino-

derm species do not appear to be related to any previously characterized families. In addition to the regulation of endogenous enzymes, proteinase inhibitors may protect invertebrates from exogenous proteinases produced by, for example, entomopathogenic fungi. Finally, other inducible effector factors elicited by toxins represent interesting avenues for future research in invertebrate immune responses. Cockroaches injected with toxoids from bee or snake venom acquire resistance to the otherwise lethal toxins. This response is accompanied by the appearance in the hemolymph of a 102 kDa molecule which precipitates the toxins. Responses to the two toxoids are purported to be specific, and an anamnestic response has also been postulated.

Regulation of recognition/effector responses

Recruitment and activation of effector cells that initiate the acute phase response are mediated in vertebrates by cytokines such as interleukins 1 and 6, and tumor necrosis factor α (TNF α). In starfish and tunicates, cytokine-like activity (presumably mediated by factors equivalent to IL-1 and IL-6) has been identified. So too have specific receptors on phagocytic cells. Invertebrate putative cytokine-like factors may participate in the regulation of non-specific responses to tissue damage and infection. If these factors are homologous to the vertebrate equivalents, additional roots of the vertebrate immune system may be detected within invertebrate phyla of the deuterostome lineage, from which vertebrates are considered to have arisen.

Chemotaxis and cell adhesion may be modulated in invertebrates by opioid peptides, opiate alkaloids and other neuropeptides. There is evidence of these factors and their receptors in the mussel *Mytilus edulis*. At the genetic level, however, *Drosophila* has resulted in the best model system for analyzing the regulation of immune responses: at least ten genes coding for antibacterial peptides have been cloned and structurally characterized. Their transcriptional profiles and the control of their expression during the immune response have been defined. The *cis*-regulatory elements appear to be homologs of promoter regions of mammalian acute phase response genes, such as NF-IL6, IL6-RE BP, κ B-related, Oct 1, NF-ELAM1 and HNF5. It appears that several inducible transactivating factors are involved in the coordinated expression of insect immune genes and some share characteristics with the *rel*-related systems, namely the factor NF κ B and the *dorsal* morphogen.

Conclusions

Beyond the intellectual interest in function and evolution of invertebrate immune systems, from the practical standpoint there is a clear need to address a variety of problems related to disease prevention and remediation for economically and ecologically important invertebrate species, as well as those that serve as vectors of disease to humans. Marine and freshwater fisheries and aquacultured crustaceans (shrimp, prawn and lobster) and molluscs (oysters, mussels and clams) now constitute significant sources of food, employment and commerce. Despite considerable improvements in the design and implementation of production techniques, the ability to prevent mass mortalities due to viral, bacterial and protozoan epizootics has not made comparable progress; catastrophic losses in productivity are becoming increasingly frequent. There is a continuing need for intense research in this area.

IRIDOVIRUS, INFECTION AND IMMUNITY

Stephanie K Watson and James Kalkmakoff, Department of Microbiology, University of Otago, Dunedin, New Zealand

The Iridoviridae family of viruses are large, icosahedral, double-stranded DNA viruses that infect a wide range of both vertebrate and invertebrate hosts. This family currently consists of five recognized genera (Table 1) with the iridoviruses being those that infect invertebrates (mostly insects). To date 33 iridoviruses have been classified with major studies being carried out on *Tipula* iridescent virus (TIV), *Chilo* iridescent virus (CIV) and *Wiseana* iridescent virus (WIV). The term 'iridescence' stems from the blue hue initially observed in the TIV-infected larvae of the crane fly *Tipula paludosa*; however, this phenomenon is not consistent with all infections.

Characteristics of iridoviruses

Virion structure

Virions are comprised of an icosahedral outer capsid, an internal lipid membrane and an electron-dense central core which contains the viral DNA. The capsid is made up of a single polypeptide of about 50 kDa in size, which is approximately 40% of the total mass of the virus. This protein has been shown to be highly conserved throughout the Iridoviridae family and therefore is of use in comparison studies. The tight packing of these icosahedral capsids can form a crystalline array (Figure 1) which diffracts

Table 1 Classification of the Iridoviridae family

Genus	Vernacular name	Host species	Type species
<i>Iridovirus</i>	Small iridescent insect virus	Diverse invertebrates (mostly insects)	<i>Chilo</i> iridescent virus (CIV)
<i>Chloriridovirus</i>	Large iridescent insect virus	Diptera (mosquitoes)	IV Type 3 from <i>Aedes taeniorhynchus</i>
<i>Ranavirus</i>	Frog virus	Amphibia	Frog virus 3 (FV3)
<i>Lymphocystivirus</i>	Lymphocystis disease virus	Fish	Lymphocystivirus type 1 (LCDV-1)
Goldfish virus-like	Goldfish virus	Goldfish	Goldfish virus (GFV-1)

Figure 1 Electron micrograph of *Wiseana* iridescent virus. Cross-section of an infected insect showing virions in a crystal-line array.

light, causing a distinctive iridescence; however, this phenomenon has no biological significance.

The number of proteins detected for each iridovirus varies depending on the method and conditions of analysis. CIV has been shown to consist of at least 20 polypeptides, ranging from 10 to 213 kDa, with reports of up to 50 polypeptides by two-dimensional gel electrophoresis. Structural polypeptides of TIV have been shown to be nonglycosylated. Closely associated with the capsid is the internal lipid membrane, through which proteins pass, connecting the outer capsid to the inner core polypeptides. The lipid composition of the iridovirus membrane differs significantly to the lipids of the host cell membrane, indicating that their synthesis is virally encoded. The inner core is highly hydrated and comprises DNA packed with DNA-binding proteins. The DNA is linear, double stranded and nonmethylated and exhibits cyclically permuted terminal redundancy. CIV has a terminal redundancy in which 12% of the genomic DNA is repeated at the termini of the genome. This

feature is unique for eukaryotic viruses and it is more commonly observed in prokaryotic viruses such as the bacteriophages T4 and P22.

Host range and classification

Iridoviruses vary in their host range: some exhibit a broad range of host species while others are restricted to one or two specific hosts. Both TIV and CIV have a wide host range, infecting dipteran, coleopteran and lepidopteran hosts. CIV has been shown to infect over 100 insect species, woodlice, centipedes and two species of Crustacea. The greater wax moth *Galleria mellonella* (Lepidoptera: Pyralidae) is highly permissive to most iridoviruses and is used for general virus propagation. Iridoviruses infecting insects have not been found to infect any vertebrates. The current classification scheme for these viruses uses names according to the host species of initial isolation and a type number relating to the chronological order of discovery. A system using PCR sequencing and DNA–DNA hybridization methods is currently being investigated for classification of iridoviruses.

Replication

These viruses have a low pathogenicity and the frequency of subclinical infections (those not exhibiting iridescent coloration) is probably high. Cannibalism and wounding are the likely routes of infection, although entry via spiracles, transovarial transmission and ingestion have also been proposed. The iridescence of infected individuals is not a reliable diagnostic criterion and has in the past lead to many false, negative results. The primary site of infection is thought to be the hemocytes and fat bodies of the larvae, with eventual spread to the entire body via the hemolymph. Virus particles enter the insect cell via phagocytosis and are incorporated into lysosomes where the virus is uncoated and replication initiated. Frog virus 3, isolated from the leopard frog *Rana pipiens*, has been shown to synthesize viral

Figure 2 Electron micrograph of a *Wiseana* iridescent virus-infected *Spodoptera frugiperda* cell. Arrow indicates region of virus assembly in the cell cytoplasm. N, cell nucleus.

DNA in two stages. DNA is first synthesized in the cell nucleus in genome lengths, then transported to cytoplasm where it is replicated as a large concatemer of DNA. This two-step replication of DNA is a feature unique to the Iridoviridae family and it enables the linear genome to be replicated completely, resulting in the headful packaging of DNA and the terminal redundancy. Capsids are preformed in the cytoplasm where packaging occurs (Figure 2) and complete virions can be released via budding from the cell membrane or by cell lysis. Iridoviruses induce a shutdown of host macromolecular synthesis while utilizing some machinery for replication. This shutdown eventually leads to host death, although not until the individual is highly infected: in some cases up to one-third of the insect body weight can be virus.

Virus–host responses

The immune system of the insect is simple in comparison to that of the vertebrate. Primarily there is a cellular response comprising phagocytosis, encapsulation, nodule formation or coagulation to recognize 'foreignness'. Inducible substances such as attacin, cecropins, lysozyme and phenol oxidase have been isolated from a variety of dipteran and lepidopteran species and may play a toxic role in the defense mechanism. There is no evidence of specific antibody–antigen reactions, a complement system or interferon and any immunity is short lived and of a nonspecific nature. As infection predominantly

occurs in the insect larval stage, which exists for about 3 weeks, there is little reason for the evolution of an acquired immune system. CIV has been shown to encode a putative apoptosis-inhibiting factor, thus enabling the virus to prevent the programmed death of a cell in response to infection. In general, iridovirus infection of insect populations is a welcome occurrence as they are seen as a form of biological control. However, infection of a honey bee species is of concern to the honey industry. Within the Iridoviridae family there are also examples of viruses that infect fish, lymphocystis disease virus (LCDV-1), and frogs (FV3) which are important to both the fisheries industry and environmental agencies. However, the immune response to infection with these viruses remains to be investigated in both fish and amphibians.

IRON AND THE IMMUNE SYSTEM

AR Sherman, Department of Nutritional Sciences, Cook College, The State University of New Jersey, New Jersey, USA

Iron deficiency is the most common nutritional deficiency in populations around the world, especially in women, infants and children. In addition to the role of iron as an integral component of many proteins and as a cofactor for enzyme systems, it appears to be active in the immune response. Both iron deficiency and iron excess can alter immunocompetence (Table 1).

Effect of iron status on immunocompetence

Iron has a dual role in its association with immune function. First, micronutrients, such as iron, are redistributed in the body during infection. Second,

dietary deficiency of iron causes iron-deficiency anemia and decreased immunocompetence. The effects of iron excess depend on the route of entry of iron.

Iron is required for growth and proliferation of microorganisms. Upon invasion of a host by bacterial microorganisms, iron is rapidly redistributed in the host to stunt proliferation of bacteria by removing iron from circulation and storing it in organs, such as the liver and spleen. Redistribution of iron during infection can be misinterpreted as iron deficiency anemia by hemoglobin and hematocrit measurements. Upon recovery from infection, the iron status of the host will return to normal, assuming that iron status was normal before the onset of infection. This redistribution of iron during

Table 1 Effects of iron status on immune response components

Immunity	Effect of iron deficiency	Effect of iron overload
Immunocompetence		
Response to infection	↓ (humans)	↑ (humans, rats)
Growth of <i>E. coli</i> and <i>S. aureus</i>		↑ (humans)
Humoral Immunity		
Antibody production	↑ (humans), ↓ (rats)	
IgM response to sheep red blood cells		↓ (mice)
Opsonization		↓ (humans)
Cell-mediated Immunity		
Cellularity of spleen/thymus	↓ (rats)	
Circulating T cells	↓ (humans, mice)	
B and T cell response to mitogens	↓ (humans, rats, mice)	↓ (humans, mice)
Hypersensitivity response	↓ (humans, mice, guinea pigs)	
NK cell cytotoxicity	↓ (rats, mice)	↓ (humans)
CD8 T cells		↑ (humans)
Granulocyte phagocytosis		↓ (humans)
Cytokine production		
Macrophage inhibitory factor	↓ (humans)	
Interferon	↓ (rats)	
Interleukin 1	↓ (rats)	
Interleukin 2	↓ (humans)	

infection has a protective role for the host. Repletion of iron in malnourished children of poor populations by injection of iron dextran or oral iron supplements has been found to increase the incidence of infection. The excess iron was most likely increasing bacterial proliferation rather than altering immunocompetence.

Effect of iron deficiency on susceptibility to infection

Decreases in response to infection have been demonstrated in iron-deficient humans and animal models. The first study of the effects of iron deficiency on susceptibility to infection in infants was conducted in the late 1920s by Mackay, who recommended the use of iron fortified cow's milk. Iron fortification resulted in increased hemoglobin concentration and a 50% reduction in respiratory and gastrointestinal infections. In the multitude of studies conducted over the past 70 years, children with iron deficiency have demonstrated either increased or unchanged morbidity. Some studies support the hypothesis that iron deficiency may protect against certain infections. Increased infections after high-dose iron supplementation and/or a hypoferremic response in the host after microbial invasion have been documented in both humans and rats. Conflicting results are probably due to differences in experimental design, methodology and data collection. The presence of health and nutritional problems, as well as differences in socioeconomic conditions, contributes to variations in results.

In a number of clinical studies using different population groups, impairments in chemotactic activity and bactericidal capacity, and in the generation of an oxidative burst by the hexose monophosphate shunt have been reported in neutrophils of noninfected iron-deficient children compared with age-matched controls. No defects in opsonization and phagocytosis were found in iron-deficient subjects. Generation of an oxidative burst and bacterial capacity could be restored with 2 weeks of oral or parenteral iron treatment. In peripheral blood of iron-deficient rat pups, generation of an oxidative burst in phagocytes was decreased even though the percentage of phagocytes was increased. Myeloperoxidase, an iron-containing oxidative enzyme, has been reported to be either normal or decreased in iron deficiency. Defective destruction of organisms by oxidative substances normally produced in the myeloperoxidase pathway may contribute to decreased bactericidal capacity of phagocytes during iron deficiency.

The iron chelator desferrioxamine has been shown

to have antiproliferative effects on tumor growth and infections such as malaria. These observations are likely to be due to the direct action of the desferrioxamine, and not to its iron-chelating ability.

Effect of iron deficiency on humoral immunity

Iron-deficient children demonstrate either normal or elevated basal or stimulated antibody production to diphtheria and tetanus toxoid antigen, suggesting that humoral immunity is not impaired by iron deficiency. In contrast, use of a Jerne plaque assay in iron-deficient rat pups revealed decreased antibody formation to sheep red blood cell antigen. Dietary repletion of pups improved iron status, but did not correct immunoglobulin M (IgM) and IgG antibody production. Maternal iron deficiency resulted in irreversible impairment of antibody production which was not corrected by short-term iron repletion. Human implications of these findings in rat studies are important because many pregnant women develop iron deficiency.

Effect of iron deficiency on cell-mediated immunity

Cellular immunity is impaired in animals and humans with iron deficiency. Cellularity of immune tissues, such as spleen and thymus, is decreased in iron-deficient neonatal rats, and not easily repaired by iron repletion. A decreased percentage of circulating T cells has been found in iron-deficient children and mice. A decreased blastogenic response of T cells to concanavalin A and phytohemagglutinin and/or B cells to lipopolysaccharide has been found in iron-deficient humans and rodents. Since the iron-dependent enzyme ribonucleotide reductase is required for DNA synthesis, decreased cell proliferation may be due to decreased DNA synthesis. A depressed delayed hypersensitivity response has also been found in adult humans, mice and guinea pigs with iron-deficiency anemia.

Natural immunity against malignancy may be impaired in iron deficiency. Rat pups from iron-deficient dams have impaired peritoneal macrophage cytotoxicity. In iron-deficient rats and mice, decreased capacity of stimulated natural killer (NK) cells to kill tumor cells has been reported. Iron deficiency may decrease the responsiveness of effector cells toward the target tumor cells, decrease the percentage of effector cells capable of killing, or decrease the functional capacity of effector cells to kill once activated.

Effect of iron deficiency on cytokine production

Interferon is a cytokine that is produced by macrophages and activates NK cell cytotoxicity against virus-infected cells or tumor cells. Interferon added *in vitro* does not restore the cytotoxic capacity of iron-deficient NK cells to control levels. It appears that the functional capacity of interferon as a mediator of cellular immunity is altered by iron deficiency. Interleukin 1 (IL-1) is an important regulator of the acute phase response to an infection. Production of IL-1 by peritoneal cells is decreased in iron-deficient rats. IL-1 stimulates T cells to produce IL-2. Iron deficiency in children, and in rats, causes a decrease in IL-2 production. Decreased production of macrophage inhibitory factor has been demonstrated in adults with iron deficiency anemia.

Effect of iron excess on immunity

Iron excess has been associated with increased susceptibility to infections and abnormal neutrophil and lymphocyte function. Patients with iron overload undergoing dialysis showed decreased phagocytosis and bactericidal capacity of blood neutrophils. Hemochromatosis patients with elevated levels of storage iron were reported to have elevated numbers of CD8 T cells and impaired ability of peripheral blood mononuclear cells to respond to mitogens. Increased transferrin saturation in cancer patients receiving chemotherapy has been associated with increased *in vitro* growth of *Escherichia coli* and *Staphylococcus aureus*. NK cell cytotoxicity against K562 target cells was decreased in patients with β -thalassemia major who are iron overloaded as a consequence of chronic transfusion therapy. In patients with β -thalassemia intermedia, decreased opsonization and granulocyte phagocytosis, decreased serum immunoglobulin levels, and changes in B and T cell numbers and function have

been reported. Iron-loaded mice were reported to have reduced IgM antibody response against sheep red blood cells, but no changes in IgG antibody response were seen. Iron-loaded mice exhibit impaired mononuclear cell responses to various mitogens.

Conclusions

A number of studies have demonstrated that iron deficiencies and states of iron excess compromise the immune system. Further research needs to concentrate on biochemical, metabolic and genetic aberrations caused by altered iron status to discover the mechanisms causing compromised immunocompetence associated with altered iron status.

ISCOM (IMMUNO-STIMULATING COMPLEX)

B Morein, Department of Veterinary, Section of Virology, Swedish University of Agricultural Sciences, Uppsala, Sweden

ISCOM is a delivery system for antigen and adjuvant together in the same particle. The unique component of ISCOM is a mixture of *Quillaja* saponins extracted from the bark of the tree *Quillaja saponaria* Molina. Three groups of *Quillaja* components

with a triterpenoid structure (QH-A, QH-B and QH-C) have been characterized by reverse-phase high-pressure liquid chromatography (HPLC) and have been functionally identified to be of particular interest for ISCOMs. They differ in terms of adjuvant

activity, ISCOM-forming capacity and toxicity. A defined composition of QH-A and QH-C called Iscoprep 703™ is now used in ISCOM vaccines in human clinical trials.

The ISCOM system was first created to make antigens optimally immunogenic by:

1. presenting the antigens in a physically immunogenic form, i.e. several copies in a submicroscopic particle to resemble that of an infectious agent;
2. optimizing the targeting of antigen and adjuvant to lymphatic organs and lymphoid cells by enclosure of adjuvant and antigen in a stable, uniform particle;
3. optimizing the immunomodulatory capacity by presenting the adjuvant and antigen components in the same particle, thus reducing the amount of antigen and adjuvant required to enhance the immune response.

Preparation of ISCOM–antigen complexes

ISCOM is composed of a matrix (Figure 1) contain-

ing *Quillaja* saponins, cholesterol and phospholipid at a molar ratio of about 1:1:1. The assembly of ISCOM is facilitated by hydrophobic interaction between these components and the antigen. The ISCOM antigen may be an envelope protein of a native virus, a cellular membrane protein, or peptides containing hydrophobic domains or any antigen with a hydrophobic domain. In the case of virus, the envelope is disintegrated by a detergent, preferably nonionic, to release a protein–detergent complex (Figure 1). Upon the removal of the detergent (e.g. by dialysis or density gradient centrifugation) in the presence of *Quillaja* saponins, cholesterol and additional lipid, ISCOM assembly takes place. Primarily nonamphipathic proteins (e.g. gp120 of human immunodeficiency virus (HIV)) may also be integrated into ISCOM by refolding the protein to expose certain hydrophobic sequences, which are then available to form hydrophobic interactions. By efficient coupling methods, peptides may be conjugated to the external protein moiety of an ISCOM, which will then act as a carrier providing T cell help for a peptide antigen.

Electron microscopic analysis of ISCOMs shows

Figure 1 (A) Schematic representation of the disintegration of a viral envelope by a detergent, thus releasing a protein–detergent complex. By removal of detergent, in the presence of cholesterol, phospholipid and *Quillaja* saponin, the amphipathic proteins are assembled into a symmetrical shell of globular subunits. (B) Electron micrographs of ISCOM particles containing HIV proteins (arrows indicate hexagonal outline of subunits).

Table 1 Protective immunity induced by ISCOMs containing proteins derived from various microorganisms

Protein	Animal	Disease
Hemagglutinin (H) and neuraminidase (N) of influenza virus	Mouse Horse	Pneumonia, fatal Pneumonia, general infection
Glycoprotein of rabies virus	Mouse	Fatal
Measles virus hemagglutinin (H) protein	Mouse	Encephalitis, fatal
Measles virus fusion (F) protein	Mouse	Encephalitis, fatal
Bovine virus diarrhea virus	Sheep	Abortion
Feline leukemia virus	Cat	Viremia
Epstein-Barr virus	Tamarin monkey	Tumor
Equine herpes 1 virus	Hamster	Lethal
Equine herpes 2 virus	Horse	Pneumonia
Bovine herpes 1 virus	Cattle	Pneumonia
Pseudorabies virus	Lamb	Lethal
Pseudorabies virus	Swine	Weight loss, illness
Herpes simplex 1 virus	Mouse	Lethal
Herpes simplex 2 virus	Mouse	Lethal
gp120 of SIV	Monkey	Lethal infection
gp125 of HIV-2	Monkey	Viremia
gp120 of HIV-1	Monkey	Viremia, challenge with a chimeric HIV-1/SIV

40 nm cage-like structures exhibiting icosahedral symmetry with a number of morphological subunits. Multiple copies of antigens are exposed on the ISCOM particle. The construct is physically remarkably stable; it can be frozen and freeze-dried and dissolved in various buffers. Lyophilization may thus be useful for storage of ISCOM vaccines.

Immunogenicity of antigens borne by ISCOMs

Antibody-mediated immunity is efficiently induced by parenteral administration of antigens included in ISCOMs. In mice, the immune response was found to be a classical one, with an initial immunoglobulin M (IgM) response followed by an IgG response. The IgG response is distributed in all subclasses but the IgG2a response is dominant. In general, the antibody response to an antigen in an ISCOM is about 10 times higher than that induced by the same dose of the killed virus particles in saline or in micellar form.

After local intranasal administration of the hemag-

glutinin or neuroaminidase envelope proteins of influenza virus in ISCOMs, a high serum antibody response of the same order of magnitude as that following parenteral immunization was observed. A secretory IgA response is also efficiently evoked after intranasal immunization both at local respiratory mucosa and distant, e.g. genital tract, mucosa. In general, antigens derived from virus envelopes or cell membranes incorporated into ISCOMs retains biological activity and conformation provided their isolation is carried out under mild conditions. Thus, the biological activities of influenza virus surface glycoproteins borne by ISCOMs are conserved, facilitating the penetration of mucus, which explains their efficiency in evoking mucosal immune responses.

ISCOMs efficiently stimulate antigen-presenting cells (APCs) to produce interleukin 1 (IL-1) and IL-12. Other cytokines such as IL-6, granulocyte-macrophage colony-stimulating factor (GM-CSF) and tumor necrosis factor α (TNF α) are also induced. The ISCOM induces strong T cell responses of the T_H1 type characterized by delayed-type hypersensitivity (DTH) and enhanced production of interferon γ (IFN γ) and IL-2, while IL-5 is enhanced IL-4 is not generally enhanced and IL-10 is downregulated. In general, ISCOMs are excellent inducers of IL-2 and IFN γ .

ISCOMs efficiently induce antigen-specific cytotoxic T lymphocytes (CTLs) following either parenteral or mucosal routes of administration. It appears that the protein antigens contained in ISCOM can be delivered not only to endosomes but also to the cytosol of APCs, leading to cytosolic processing, transportation to the endoplasmic reticulum, presentation by major histocompatibility complex (MHC) class I molecules to T cells, and a subsequent CD8⁺ T cell response. For example, ISCOMs containing the gp160 of HIV-1 have been shown to induce MHC class I restricted CD8⁺ CTLs. The induction of relevant cytokines such as IL-12, IL-2 and IFN γ is an additional benefit.

Protective immunity has been induced against a variety of microorganisms including viruses, bacteria, mycoplasma and parasites. Of particular interest is that protective immunity was induced by ISCOM-borne antigens to a number of retroviruses, e.g. feline leukemia virus infection in cats, to SIV, HIV-1 and HIV-2 in primates, to a tumor-inducing herpesvirus (e.g. Epstein-Barr virus) in cotton top tamarin monkeys, and against lethal infection of mice with *Trypanosoma cruzi* causing Chagas' disease in humans. Table 1 lists examples of ISCOM-borne antigens having induced protective immunity.

ISOELECTRIC FOCUSING

Maryvonne DR Brasher and **Robin Thorpe**, Division of Immunobiology, National Institute for Biological Standards and Control, Hertfordshire, UK

Isoelectric focusing (IEF) is an electrophoretic procedure capable of extremely high resolving power. During IEF, zwitterionic molecules are separated according to their isoelectric point (pI; defined as the 'pH at which a zwitterion possesses no overall charge'), and the technique can therefore be used to analyze the composition of a mixture and/or to determine the precise pI of a component under investigation. Although usually applied to proteins or protein-containing extracts, the method can, at least theoretically, be used for analysis of any zwitterionic species. Methodology has been developed to allow IEF to be carried out on analytical and preparative scales.

Principles

The underlying basis of IEF can be simplified to the following principles. If a zwitterion is not at its pI it will, by definition, possess an overall charge that will depend upon the pH of its environment and the number of ionizable chemical groups (especially carboxyl and amino residues) contained within its structure. When subjected to an electric field, it will move toward one or other of the electrodes depending upon the polarity of the charge on the molecule, which is in turn dependent upon the surrounding pH. If a pH gradient is established between the electrodes, then the zwitterionic molecule will migrate toward the electrode of opposite charge to that on

the molecule. As it moves along the pH gradient, the charged chemical groups responsible for the overall charge will be neutralized by the increasing concentration of oppositely charged ions derived from the surrounding environment. Eventually, all of the charged groups on the zwitterion will be neutralized and, as it will then possess no overall charge, it will no longer migrate in the electrical field, but will 'focus' or 'condense' into a tight band. The precise pH at which the molecule is focused is, by definition, the pI of the zwitterion as it is the pH at which it is electrically neutral, i.e. possesses no overall charge. The zwitterion will remain at this focused position as long as the pH gradient and electric field are maintained; IEF is, therefore, unlike most electrophoretic techniques, a 'steady-state' procedure.

Although a pH gradient will automatically form as the result of the application of an electric field to an H⁺ containing ionizable solution, such gradients are insufficiently robust or stable to be used experimentally for IEF. The problem of producing suitable pH gradients was the major technical difficulty experienced by pioneers of IEF such as Svensson, and delayed its introduction as a routine laboratory procedure for many years after its theoretical potential was realized (see Righetti, 1983, for a more detailed discussion of the principles of IEF and its early development).

In the mid-1960s, this problem was overcome by Vesterberg, who chemically synthesized a complex mixture of poly amino carboxylic acids which, when subjected to an electrical field, formed an array which produced a pH gradient. He was able to form fairly linear pH gradients over the range 3–10 and these were found to be suitable for IEF.

Methodology

Although it is possible to chemically synthesize poly amino acids suitable for IEF in the laboratory, most biologists now rely on commercial suppliers for these reagents. Such compounds are usually referred to as 'carrier ampholytes' and their function is to produce a stable, linear pH gradient when subjected to an electrical field. They are almost always poly amino acids, but several different chemical backbones to support the charged groups have been developed. The precise pH gradient obtained depends on the spectrum of ampholytes used. The commercial supply of carrier ampholytes was monopolized for many years by LKB, who almost certainly reproduced Vesterberg's synthesis of polyprotic amino carboxylic acids on a commercial scale. The LKB ampholytes are marketed under the trade name 'Ampholines' and are available for wide range gradients (pH 3.5–10.0)

and are also subfractionated using IEF itself to produce various narrower range gradients.

In the late 1970s, other commercial sources of chemically distinct carrier ampholytes became available, e.g. 'Pharmalytes' (Pharmacia) and 'Servalytes' (Serva), which are also available in wide and narrow pH ranges ('Ampholines', 'Pharmalytes' and other more recently developed ampholytes are now marketed by Pharmacia Biotech). Although pH gradients produced using such commercial ampholytes are in general linear and stable, 'weak spots' may occur at some pI values, particularly near the anode and cathode. For this reason, some workers prefer to add acids, bases or additional ampholytes such as arginine, lysine, glutamic and aspartic acids to strengthen these parts of the gradient. For most purposes, ampholytes are used at a final concentration of 1–2% w/v.

For practical purposes, it is necessary to provide some way of protecting the pH gradient (and focused proteins) from physical disruption during focusing and particularly during analysis. This is achieved by different means according to the procedure used. Isoelectric focusing was originally carried out on both analytical and preparative scales in the liquid phase using vertical glass columns. This apparatus usually consists of a central cylindrical compartment for focusing and electrode chambers at either end; these chambers contain platinum electrodes which are connected to a power supply. The focusing chamber is cooled using a water jacket connected to a chiller. Commercially available columns are equipped with a system which allows careful filling of the electrode chambers and ampholytes and a density gradient of an inert, nonionic substance (e.g. sucrose, glycerol, ethylene glycol) is used to prevent convection and mixing.

Prior to focusing, the lower chamber is filled with an electrode solution suitable for the required polarity (the anode is usually chosen for the lower electrode); this contains the highest concentration of anticonvection substance. The ampholyte solution is then prepared in low and high concentrations of anticonvection agent and this is pumped into the focusing chamber using a gradient former to produce a linear density gradient which decreases from the bottom to the top of the chamber. As IEF is a steady-state process, which 'condenses' the focused components of the preparation under study, it is not necessary to apply the sample in a small volume or as a thin band; the sample can be added to a portion of the ampholyte/anticonvection agent solution or even included in the whole of the focusing solution. When the focusing chamber is full, it is overlaid with electrode solution compatible with the upper

electrode. Electrode solutions are usually dilute acids or bases such as NaOH (cathode) and H_2SO_4 or H_3PO_4 (anode). For narrow range IEF weaker acids, aliphatic amines or ampholytes are more appropriate as electrode solutions.

When the column filling procedure is completed, IEF is carried out by applying a potential difference between the electrodes. At first the current is fairly high as the ampholytes arrange themselves to form the pH gradient; after this the current falls so that when the steady state is reached only a very small current flows. As the applied voltage concentrates the focused bands, it is usual practice to increase the voltage during focusing so that resolution of components is maximized. Although this can be done manually, it is easier and probably better to use a constant-power pack which automatically increases the voltage during IEF. The voltages required for high-resolution IEF are usually higher than for other types of electrophoresis. Column IEF is normally carried out overnight or for even longer. When focusing is complete, the contents of the focusing chamber are carefully removed either under gravity or using a pump, and fractions are collected for analysis. This usually involves the detection of biological material (e.g. protein) and/or assay for biological activity (e.g. enzyme or immunological activity).

Although column IEF has some advantages – for example, fractions can be assayed for several different parameters and it can be carried out on a fairly large scale (commercial columns of 110 and 440 ml are available) – it also suffers from several disadvantages. These are that it is laborious, expensive (considerable quantities of ampholytes are required), it is time-consuming, only one sample can be analyzed per experiment, and fractions may become mixed during collection. For this reason, alternative anticonvection devices have been developed, particularly for analytical IEF.

A particularly useful analytical approach is to use polyacrylamide gel as a solid support for IEF. For this, a gel is prepared in water containing ampholytes. Either slab or rod gels can be used: the former is normally carried out horizontally, whereas for the latter a conventional disk electrophoresis apparatus is used. Electrodes for slabs consist of carbon rods soaked in acid or base or platinum wire in contact with acid- or base-soaked filter paper. For rod gels, dilute acid or base is used to fill the electrode chambers. Samples are applied directly to the gel surface or absorbed on to filter paper strips; other details are as for column IEF. After focusing, proteins are identified by staining with dye (e.g. Coomassie Blue) or by detection of biological activity (e.g. enzyme activity or immunoreactivity).

Other useful anticonvection devices are agarose gel (low electroendosmosis agarose is required as 'ordinary' agarose or agar is charged and therefore unsuitable for IEF) and Sephadex slurries. Both of these (especially the latter) can be used for preparative IEF as focused protein can be eluted from the gel and recovered in the supernatant after low-speed centrifugation. The use of agarose for IEF allows higher molecular weight proteins (e.g. IgM) to readily enter the gel, which does not occur if polyacrylamide gel is used. For reasons still not entirely clear, a phenomenon known as 'cathodic drift' occurs with gel IEF in which the pH gradient slowly collapses into the cathode; for this reason, focusing time for gel IEF is fairly short.

Modifications to the basic procedure have been devised to allow IEF analysis of proteins which are insoluble under physiological conditions, e.g. membrane and cytoskeletal proteins. These involve the use of denaturing agents such as deionized urea and/or nonionic detergents (e.g. Nonidet P-40).

Uses of IEF

Analytical IEF can be used to assess the complexity of protein extracts and to identify components of interest. However, the great resolving power of IEF makes it ideal for detection of microheterogeneity in purified proteins. Enzymologists have used IEF to detect isoforms of purified enzymes and protein biochemists have demonstrated 'multiple forms' of many proteins which appear homogeneous using other biochemical techniques (including other electrophoretic methods). Focusing is used for the diagnosis and study of some genetically transmitted disorders. The basis of the slight differences in the pI of isoforms as revealed by IEF is often post-translational modification of a protein, i.e. a single primary structure which is modified after synthesis. This is frequently due to variation in the glycosylation of a protein and, in particular, the number of sialic acid residues present. Immunochemists often use IEF for the analysis of a variety of antigens and preparations. The technique is very useful when combined with immunoblotting; this enables the precise antigen-binding profile of an antiserum or monoclonal antibody to be established.

Isoelectric focusing has been used to demonstrate the microheterogeneity of immunoglobulins. Thus focusing of immunoglobulin G (IgG) derived from whole serum produces a 'smear' of protein over a fairly wide pH range due to the very large number of different immunoglobulin molecules present; IEF of affinity purified IgG usually shows a complex multiband pattern. The focusing of murine mono-

Figure 1 Isoelectric focusing in polyacrylamide gel of different purified IgG mouse monoclonal antibodies.

clonal antibodies shows different IgG species to possess very different pI values and that the mAbs can show variable microheterogeneity (see **Figure 1**). The microheterogeneity is very often due to differences in glycosylation, but other post-translational modifications of the monoclonal IgG molecule also produce multiple bands on focusing. The IEF profile of a mAb can be useful for identification purposes and is sometimes referred to as the 'spectrotype' of the antibody. Focusing can be used to demonstrate the presence of oligoclonal immunoglobulin in biological fluids which may be significant in certain pathological conditions, e.g. multiple sclerosis. Isoelectric focusing is also used for analysis of the polymorphism of the major histocompatibility complex.

Isoelectric focusing is often used as part of the quality control testing of therapeutic biological products to demonstrate batch consistency. Its high resolving power and ability to detect subtle changes in charge of proteins is particularly valuable for this (see **Figure 2**).

Preparative IEF is used for isolation of proteins and is usually included at a later stage of a purification procedure, to separate a specific component from contaminants of slightly different pI. It is usually the method of choice for the preparation of isoforms of proteins.

An important development of the basic polyacrylamide gel IEF procedure described by O'Farrell in 1975 is the concept of two-dimensional electrophoresis. For this, proteins are initially separated using IEF in rod gels and then the rods are overlaid at a right angle on an SDS-PAGE gel and subjected to secondary separation. This technique is particularly powerful as first-dimensional separation is on the basis of fine differences in charge, whereas second-dimensional resolution is size dependent. It is possible to resolve more than 1000 individual proteins in an extract using this method.

A preparative procedure related to but distinct from IEF known as 'chromatofocusing' was introduced in the early 1980s. The principle of the tech-

Figure 2 Isoelectric focusing in polyacrylamide gel of a number of batches (lanes 2-15) of clinical grade erythropoietin, showing consistency of production. All batches show an identical spectrotype and the IEF pattern matches that produced by the reference standard (lanes 1 and 16). The pH values at points measured on the gradient are shown on the vertical axis.

nique is that proteins will be focused on an ion-exchange column if there is a pH gradient formed along the length of the column, and they will be eluted from the column at a pH value near to their individual pIs. A mixture of acids, bases and ampholytes are used to form the gradient and equipment and reagents for chromatofocusing are available commercially. The procedure has the advantages that it uses a robust solid column support and has high sample capacity.

A caution

Although IEF is a very valuable analytical and preparative technique, it can produce artifactual results. One problem is that proteins are very poorly soluble at or near their pI and so precipitation of components may occur during focusing. Also, apparently different isoforms of a protein (as revealed by focusing) can be due to conformational isomers, oxidation or reduction, or formation of complexes with other proteins or ampholytes. A good check for this is to apply the sample at different positions in the pH gradient and check for an identical pattern and to ensure IEF-isolated components retain their identity on repeated focusing.

ISOTYPE

Jacobo Abadi, Department of Pediatrics, Division of Pediatric Infectious Diseases, Albert Einstein College of Medicine, Bronx, New York, USA

Liise-anne Pirofski, Department of Medicine, Microbiology and Immunology, Albert Einstein College of Medicine, Bronx, New York, USA

Immunoglobulin (Ig) isotypes are responsible for the biological effector functions of antibody molecules. In humans, there are nine Ig heavy (H) chain and two light (L) chain isotypes which differ in the structure of their carboxy-terminal portion, or constant (C) region. The L chain isotypes, K and λ , are not known to be associated with biological functional differences. There are five H chain isotypes, or classes: IgA, IgD, IgE, IgG and IgM. Based on 95% or greater amino acid homology, IgA and IgG have two and four subclasses, respectively. C region genes are located on chromosome 14, 3' to the JH genes of the human Ig locus: C μ for IgM, C δ for IgD, C γ 1

for IgG1, C γ 2 for IgG2, C γ 3 for IgG3, C γ 4 for IgG4, C α 1 for IgA1, C α 2 for IgA2, and C ϵ for IgE. Each one of these genes encodes glycoprotein molecules with four structural components: C μ 1, hinge, C μ 2 and C μ 3. The C μ 1 interaction with the L chain C region is of importance for the structural integrity of antibody molecules. The C μ 2 regions interact through branched chain N-linked carbohydrate moieties which facilitate antibody solubility and secretion. The hinge region enables bivalent variable region antigen-binding sites to engage two epitopes: it enhances antigen binding and cross-linking, influences steric relationships between Fab sites and Fc

regions, and is responsible for antibody molecule flexibility. IgM and IgE have a C_H4 region and lack a genetic hinge, although the pentameric structure of IgM facilitates multivalent antigen binding. IgG3 has an extended hinge region encoded by several exons rather than one. IgG4 has a short, inflexible hinge that creates steric hindrance for fixation of complement. Allotypic variants, designated as Km, Am, Mm, and Gm, may exist at any of the H chain C region loci. Such allelic differences may also influence individual isotype levels and produce differences in biological activity. There are two pseudogenes (ψ) in the H chain C region locus and multiple λ light chain pseudogenes.

Complement fixation is a critical isotype function in host defense. The classical pathway is activated by C1q binding to the C₁2 region of cross-linked IgG (IgG3>IgG1>IgG2) and to the C_H3 region of IgM. C1q binds immune complexes and IgM pentamers with higher avidity than single molecules. Antibody is not required for the activation of the alternative pathway. The C_H2 and C_H3 regions of antibody molecules are responsible for Fc receptor binding to a large spectrum of host effector cells. Fc receptor binding results in aggregation, phagocytosis and lysis of antibody-coated targets. Unique Fc receptors demonstrate different specificities and affinities for individual isotypes.

Ig class switching, regulated by T and B cell differentiation factors, determines isotype commitment during B cell maturation. Developmental maturation of IgG subclasses results in a delay in the appearance of IgG2 antibodies until age 2 years. In adults, T-independent antigens such as polysaccharides often elicit isotype restricted responses which are predominantly IgM and IgG2. T-dependent antigens such as proteins primarily elicit IgG1 and IgG3 antibodies. IgG subclass deficiency, such as the physiologic IgG2 deficiency of infancy and early childhood, is frequently compensated by increased production of alternative IgG subclasses. Isolated isotype or IgG subclass deficiencies usually do not result in increased disease susceptibility, although combined deficiencies may be a risk factor for given infections.

The five major human isotypes are variably distributed. The IgG subclasses constitute 70–75% of the total Ig pool and 50% of these antibodies are located in the intravascular space. IgG antibodies are the predominant isotype of the secondary antibody response and through a transcytosis-mediated process are the only Igs to cross the human placenta. IgM is the predominant isotype in primary antibody responses and is typically secreted as a pentamer. It represents 10% of the Ig pool and is largely (75%) intravascular. IgA constitutes 15–20% of the Ig pool. It provides

mucosal immunity and is distributed in saliva, tears and breast milk, and respiratory, genitourinary and intestinal secretions. Secretory IgA, which is predominantly IgA2, is secreted from the extracellular matrix to the lumen by transcytosis in association with a non-Ig protein, the secretory component, which is synthesized by epithelial cells. Dimeric IgA and pentameric IgM are each associated with another non-Ig protein called the J chain. Serum IgA is mainly monomeric and of the IgA1 subclass. IgD accounts for less than 1% of human Ig and appears mainly on the surface membrane of circulating B lymphocytes. The long hinge region of IgD may play a role in B cell activation by cross-linking membrane IgD to antigen. Finally, significant levels of serum IgE are rarely found in nonallergic individuals, although it is present on the surface of basophils and mast cells. It is homocytotropic because of its presence on the surface of mast cells and basophils serving as an antigen-binding molecule. IgE appears in response to helminthic infections and in hypersensitivity reactions, allergy and asthma.

J

JOINING (J) CHAIN

Jiri Mestecky, Department of Microbiology, University of Alabama at Birmingham, Alabama, USA

Itaru Moro, Department of Pathology, Nihon University School of Dentistry, Tokyo, Japan

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Although J (joining) chain was detected earlier as a polypeptide with high electrophoretic mobility in the light (L)-chain fraction from human colostrum IgA, its existence as a third polypeptide typical of polymeric immunoglobulins (Igs), distinct from H and L chains, was established in the early seventies. Subsequent studies revealed that J chain, a glycosylated polypeptide with a molecular mass of 15–16 kDa, displays a fast electrophoretic mobility and is linked by disulfide bridges to the Fc fragment of polymeric IgM or IgA of secretory and serum (myeloma) origin. Based on the given criteria (molecular mass, fast electrophoretic mobility, characteristic amino acid composition and sequence, immunochemical cross-reactivity, and sequence of DNA) the presence of J chain has been established, with variable degrees of confidence, in polymeric Ig from many vertebrate species, including mammals (human, monkey, rabbit, mouse, pig, dog, goat, cat, cow, horse, rat, guinea pig and sheep), birds (chicken and pheasant), reptiles (turtle), amphibians (frog and toad) and fishes (catfish, sardine and shark). Recently, mRNA for J chain has been detected in various species of invertebrates, including earthworm, silkworm, spider, shrimp, crab, oyster, clam, sea squirt and sea cucumber.

Structure

Human, rabbit, cow and mouse J chains consist of 136–137 amino acid residues. The sequence analyses of J chain amino acids and/or cDNA of human, mouse, cow, pig, rabbit, bull frog and earthworm revealed a high degree of interspecies homology.

These findings, together with remarkable similarity in physicochemical properties and interspecies cross-reactivities, suggest that many of the J chain features are conserved through evolution. J chains are rich in acidic (aspartic, glutamic) amino acid residues and low in the content of glycine, serine and phenylalanine; tryptophan is absent. Six of the eight cysteine residues form three intrachain disulfide bridges; two residues close to the N-terminus are involved in disulfide bonds that link J chain to the penultimate cysteine residues of α and μ chains. These residues are present in the C-terminal segments of α and μ chains which extend by 18–20 residues beyond the C-termini of γ , δ and ϵ chains. Approximately 8% of the molecular mass is contributed by a single N-linked carbohydrate side-chain that consists of fucose, mannose, galactose, glucosamine and sialic acid. Despite the low degree of sequence homology with H and L chains, studies of the secondary structure reveal that J chain folds into an eight-stranded antiparallel β barrel (with 35% β sheet and the remainder in random coil). Thus, J chain displays a secondary structure consistent with a single Ig domain. In native molecules of polymeric Ig, the antigenic determinants of J chain are poorly exposed and, furthermore, J chain, even in native Ig molecules, is highly susceptible to proteolysis; these findings may explain the failure to detect J chain in some polymeric Ig. Stoichiometric studies reveal that a single chain is present in one molecule of polymeric Ig, irrespective of the number of constituent monomers. Cleavage of interchain disulfide bonds is usually suf-

ficient for its release from Ig, suggesting that only weak noncovalent interactions exist between J chain and the Fc region of polymeric Ig.

Cellular origin

Immunohistochemical studies reveal that J chain is present in the cytoplasm, but not on the surface membrane of lymphocytes of B cell lineage at various stages of their differentiation. In tissues from healthy individuals, almost all subepithelial IgA- or IgM-producing cells of the gastrointestinal and respiratory tracts, and also the interstitium of mammary, salivary and lacrimal glands, prominently display the presence of intracellular J chain. Surprisingly, a few IgG- as well as IgD-producing cells from these tissues also contain J chain. In contrast, IgA- or IgG-containing plasma cells from the normal bone marrow are uniformly J chain negative, while cells from lymph nodes and the spleen express a variable proportion of J chain-positive cells. In multiple myeloma, IgG, IgA or IgD plasma cells in the bone marrow frequently display intense immunofluorescence, indicating the presence of this polypeptide. Similarly, J chain has been detected in IgG plasma cells from inflammatory sites and mucosal tissues, and in mitogen-stimulated peripheral blood lymphocytes. The expression of J chain in cells that are not engaged in the synthesis of polymers has been taken as a sign of their clonal immaturity. Extensive studies of human cells from leukemic patients, established lymphoid cell lines and Epstein-Barr virus (EBV)-transformed fetal bone marrow cells (depleted of surface Ig-positive cells) reveal that J chain may be expressed in the cytoplasm of lymphocytes from the earliest stages of their differentiation along the B cell axis. Thus, cells phenotypically characterized as null, pro-B or pre-B cells contain J chain, in the absence of μ chain. EBV-transformed fetal bone marrow cells or cells from a few patients with clinically established diagnosis of multiple myeloma display the morphological features of plasma cells, but contain no intracellular Ig, and in the former case, exhibit a germ-line configuration or abortive VDJ rearrangement of H chain gene segments. Recently, mRNA for J chain has been detected in T cells from human fetal thymus; peripheral T cells were negative. J chain is detectable in free form only in trace amounts in various human body fluids (urine, serum and milk) or in the supernatants of *in vitro*-cultured cells, even though these contain cytoplasmic J chain; it is not secreted unless disulfide-linked to polymeric IgA or IgM. J chain expression in B cells at early stages of differentiation is apparently different in mice, in

which J chain is detectable only in Ig-secreting cells but not in pre-B or B cells.

Sequence analyses of mouse genomic DNA reveal that J chain-encoding information is contained in four exons of a single gene located on chromosome 5; in humans the J chain gene is on chromosome 4. The expression of J chain may be upregulated by lipopolysaccharide and by interleukins, including IL-2, IL-5 and possibly IL-6.

Function

Initial findings indicated that J chain participates, directly or indirectly, in disulfide bond-exchange reactions which ultimately result in the intracellular polymerization of IgA or IgM monomers. The detection of J chain in polymeric Ig-secreting cells, the presence of cysteine residues involved in the covalent linkage to J chain in secreted but not membrane forms of the α and μ chains, correct *in vitro* assembly of IgM and IgA in the presence of J chain (which becomes incorporated) in some but not all experiments, reinforce this view. Furthermore, by fusion of IgG-secreting, J chain-positive myeloma cells with surface IgM-positive B lymphoma cells, hybrids that secrete pentameric IgM have been obtained. Contrary to these findings, site-directed mutagenesis of μ chain genes leading to the replacement of penultimate cysteine residues involved in the formation of intersubunit and J-chain disulfide bonds did not abolish the assembly of IgM polymers. Analogous results were obtained when genes encoding μ and λ chains were expressed in J chain-negative tumor cells: polymeric IgM was synthesized in the absence of J chain. The presence of J chain in cells that produce monomeric IgG or IgD remains an enigma.

Studies of the selective transport of polymeric Ig into external secretions provide convincing evidence for the essential role of J chain in the binding of polymeric Ig to secretory component (SC). The binding of polymeric IgA or IgM preparations to free or cell membrane-associated SC is proportional to their J chain content, and proteins devoid of J chain do not bind to SC. Although J chain-deficient mice produce both polymeric and monomeric IgA, the transport of polymeric forms into external secretions is greatly impaired. Thus, the SC-binding site on polymeric Ig includes J chain, in addition to constant domains of α and μ chains. Because SC also displays Ig domain secondary structure, it appears that the interactions of the component polypeptides of secretory IgA and IgM are based on complementarities of their Ig domain-like structures.

K

KALLIKREIN-KININ SYSTEM

Raul A DeLa Cadena and **Robert W Colman**, Sol Sherry Thrombosis Research Center, Temple University School of Medicine, Philadelphia, Pennsylvania, USA

The kallikrein-kinin system was first recognized as a plasma and tissue proteolytic system responsible for the liberation of the vasoactive proinflammatory mediator bradykinin (BK). However, examination of the molecular, biochemical, biological and physiological properties of the kallikrein-kinin system has shown that this system initiates or interacts with a number of physiologic and pathophysiologic systems in plasma as well as blood and vascular cells. New activities of this plasma system include protease inhibition, antithrombin function and antiadhesive properties. Tissue kallikreins are ubiquitously distributed and regulate local blood flow and glandular secretion.

Biological effects of bradykinin

The first and perhaps most important function of plasma kininogens is the delivery of BK, a potent biologically active peptide. BK itself is a potent stimulator of endothelial cell synthesis of prostacyclin and nitric oxide formation (both vasodilators and inhibitors of platelet function), phagocyte superoxide formation, tissue plasminogen activator release and

endothelial cell-dependent smooth muscle hyperpolarization factor formation. When vessels are injured, BK stimulates protein kinase C and subsequently MAP kinase, which can result in vascular smooth muscle growth and proliferation. However, when vessels are intact, BK appears to prevent vascular muscle growth and proliferation, thus keeping blood flow and vessels patent. These actions of BK are mediated through a constitutive hepta-spanning G protein-coupled receptor known as the B2 receptor. A receptor called the B1 receptor is induced by inflammatory cytokines and binds des Arg⁹-BK but its function is not yet clear.

BK plays a role in blood pressure regulation although little is known about what regulates its liberation from kininogens by tissue kallikreins. Transgenic mice overexpressing tissue kallikrein are hypotensive and lose the diurnal fluctuation of blood pressure. Intramuscular delivery of rat kallistatin, a naturally occurring serine proteinase inhibitor, reverses hypotension in transgenic mice overexpressing human tissue kallikrein. Gene delivery of tissue kallikrein reduces mean blood pressure of spontaneous hypertensive rats and this inhibition is

blocked by kallistatin. These molecular genetic studies directly indicate that presumed tissue kallikrein-induced bradykinin liberation directly modifies local and potentially systemic blood pressure regulation.

The contact system of blood coagulation

In 1975, three individuals were described with deficiency of high molecular weight kininogen (HK), a precursor of BK. All had a prolonged activated partial thromboplastin time (APTT), a surface-activated clinical coagulation screening test. Studies on the plasma kallikrein-kinin system first focused on defining the procoagulant property of HK, despite the fact that 1) none of these individuals had a hemorrhagic state and 2) it was already known that factor XII and prekallikrein deficiencies were not associated with bleeding. Factor XII and prekallikrein are required for enzymatic cleavage of HK. These plasma proteins together were grouped as the 'contact system' because of the requirement for an artificial surface for their efficient activation (Table 1).

Factor XII is produced by a single gene on chromosome 5. Activation of factor XII by plasma kallikrein, trypsin or plasmin results in an enzyme with a decreasing size, a decrease in its artificial surface-binding properties, and a decrease in its coagulant activity. There are two major forms of activated factor XII: an 80 kDa protein consisting of two disulfide-linked polypeptide chains (factor XIIa), and factor XII fragment (factor XII_f) a 28–30 kDa protein fragment derived from factor XIIa by removal of its heavy chain. Factor XII_f has no artificial surface-binding properties but retains its enzymatic ability to activate prekallikrein and the first component of the complement C1.

Prekallikrein (PK) is produced by a single gene on chromosome 4. When prekallikrein is cleaved and activated to kallikrein by either factor XIIa or factor XII_f, the active enzyme is composed of two disulfide-linked subunits: a heavy chain of approximately

52 kDa and a light chain which occurs as one of two variants of approximately 36 and 33 kDa. At least 75% of PK circulates bound noncovalently to HK. In the absence of factor XII, prekallikrein *in vitro* will not become activated on an artificial surface.

The human kininogens, HK and low molecular weight kininogen (LK) are proteins with multiple associated activities. HK and LK are the products of a single gene on chromosome 3 as a result of alternative mRNA splicing. HK has been divided into six domains. Domain 1 (which binds calcium) and D2 and D3 (which inhibit cysteine proteases including cathepsins and calpain) form the heavy chain. D4 contains BK. These domains are common to both HK and LK. D5_H which binds to artificial surfaces and D6 which binds to prekallikrein and factor XI, form the unique light chain of HK. The function of D5_L, the unique light chain of LK, is not known. The activation of the contact system can be better understood on the basis of the multiple interactions between HK and LK with cells, although the *in vivo* activating agent(s) remains unknown. Both HK and LK are known to bind to platelets, neutrophils and endothelial cells through D3, D4 and D5. On the platelet surface HK inhibits the binding of thrombin and its subsequent induction of platelet aggregation by binding to GPIb. On the neutrophil surface HK inhibits adhesion by competing with fibrinogen for binding to CD11b/CD18 (Mac-1). HK binds to several receptors on endothelial cells which mediate BK release and fibrinolysis (See below).

Activation, amplification and relationship of the contact system with other biological systems

Activation of the contact system is believed to be initiated by exposure of factor XII to negatively charged surface or cell membrane where activation of the molecule occurs. A small amount of activated factor XII (factor XIIa) can lead to cleavage and activation of its substrates: PK, factor XI and HK. PK

Table 1 Kallikrein-kinin system

Glycoprotein	Molecular weight (kDa)	Plasma concentration (μM)	Direct binding to cell surfaces
Factor XII	80	0.40	Monocytes
Factor XII _f	28		
Prekallikrein (PK)	88	0.56	
High molecular weight kininogen (HK)	120	0.66	Endothelial cells Platelets Neutrophils
Low molecular weight kininogen (LK)	65	1.30	Endothelial cells Platelets

and factor XI bind in part to cell surfaces through HK. Kallikrein can act on HK to form the active cofactor (HKa) and to release the potent nonpeptide BK. Activated factor XI (factor XIa) will, in turn, trigger the intrinsic pathway of blood coagulation. Activation of the system can be amplified, since kallikrein can activate more factor XII which in turn, will generate more kallikrein (reciprocal activation). In addition, kallikrein will generate a fragment from factor XIIa (factor XII_f) that has the ability to efficiently activate PK that is bound to HK in the fluid phase in the absence of a surface. Activation of the contact system can lead to activation of the fibrinolytic system. Kallikrein, factor XIa, and factor XII_f can generate plasmin from plasminogen *in vitro* but each of these plasminogen activators has less than 1/10 000 the plasminogen activator activity of urokinase. However, there is evidence indicating that kallikrein is an activator of prourokinase and that HKa binds to the urokinase receptor on the surface of endothelial cells, which makes the enzymatic reaction physiologically relevant.

The classical pathway of complement can be activated by the contact system. Factor XII_f can directly activate the C1r and C1s subcomponents of C1. Kallikrein itself has been shown to proteolytically cleave the C1r and C1s subcomponents of complement, leading to their inactivation. Plasminogen, which can be converted to plasmin by kallikrein-activated urokinase, has been shown to be capable of inactivation of the C1s component of C1.

Regulation of the contact system

The major plasma protease inhibitor of activated factor XIIa and factor XII_f is C1 inhibitor (C1-INH) accounting for over 90% of the inhibition of these proteases in plasma. Antithrombin III has some inhibitory activity on factor XIIa. Plasminogen activator 1 (PAI-1) also inhibits factor XIIa. The light chain of plasma kallikrein reacts with protease inhibitors, principally α_2 -macroglobulin (α_2 M) and C1-INH. Although C1-INH and α_2 M account for an equal amount of kallikrein inhibitor in plasma, C1-INH in plasma acts more rapidly than α_2 M. Antithrombin III also inhibits kallikrein but it does so slowly even in the presence of heparin. Protein C inhibitor has also been recognized to be a potent inhibitor of kallikrein. BK is rapidly inactivated by two proteases (kininases). An aminopeptidase cleaves the N terminal lysine from Lys-BK (Kallidin), converting it to BK. Carboxypeptidase N acts on BK to cleave the C-terminal arginine, yielding des Arg⁹-BK. Further degradation occurs through the action of

angiotensin-converting enzyme (a dipeptidyl carboxypeptidase) or by various aminopeptidases.

The kallikrein-kinin system in human disease and experimental models

There is increasing evidence for the role of the kallikrein-kinin system in human disease. The kallikrein-kinin system appears to exert a significant effect in various surface-mediated defense reactions including hereditary angioedema (HAE), systemic inflammatory response syndrome (SIRS), previously known as sepsis, cardiopulmonary bypass, rheumatoid arthritis and inflammatory bowel disease. HAE is a congenital condition associated with a deficiency or defect in C1-INH. Acute attacks of HAE have been well documented to be associated with activation of the kallikrein-kinin system. BK liberation is believed to be a major mediator of the edema seen in this condition. Activation of the kallikrein-kinin system has been postulated to be one of the mediators of SIRS. Historically, studies of patients with SIRS, showed that factor XII, PK and C1-INH were decreased. However, whether activation of the contact system was an early event or a result of complications associated with SIRS was not demonstrated until recently in studies with human normal volunteers given a low dose of *E. coli* endotoxin. Functional prekallikrein levels were significantly lower in the endotoxin group compared with controls as early as 2 h after infusion and remained lower throughout the rest of the experimental protocol (24 h). In an established experimental baboon model of SIRS, irreversible hypotension correlated with activation of the kallikrein-kinin system. Furthermore, treatment with a monoclonal antibody directed against human factor XII which is able *in vitro* to inhibit its autoactivation, prevented the irreversible lethal hypotension induced by *E. coli* in this experimental animal model of SIRS.

Clinical cardiopulmonary bypass (CPB) is performed on over 350 000 Americans each year. During CPB, there is an extensive contact between blood anticoagulated with heparin and the synthetic surface of the extracorporeal circuit. In simulated CPB there is a significant increase in kallikrein-C1-INH complex formation. Further studies have demonstrated that aprotinin, an inhibitor of both plasmin and plasma kallikrein, reduced blood loss after cardiac operations and decreased the elevated postoperative bleeding time. In a simulated extracorporeal bypass model, in which no plasmin is found, aprotinin decreased both kallikrein-C1-INH and C1-C1-INH complexes, resulting in a marked inhibition of the release of neutrophil elastase.

The role of the kallikrein system in inflammatory arthritis has been investigated in a model of acute and chronic relapsing arthritis induced by intraperitoneal injection of proteoglycan-polysaccharide from group A streptococci (PG-APS) into Lewis rats. In this model, PK and HK functional levels were significantly decreased. There was a striking inverse correlation between functional HK concentration and joint enlargement. Further experiments showed in this experimental animal model that rats injected with PG-APS receiving orally a potent plasma kallikrein inhibitor (P8720 or Bz-Pro-Phe-boro-Arg-OH, $K_i = 0.15$ nM) had a significant decrease (61%) in joint swelling with a disappearance of most of the dense neutrophil infiltration and mononuclear cells observed in animals not receiving P8720. The beneficial aspect of P8720 in this experimental animal model could be explained in part by prevention of BK generation from HK by the action of plasma kallikrein.

BK effects its changes in the intramuscular compartment by binding to at least two receptors, the B1 and the B2 receptors. Both of these receptors are G-coupled and this binding of BK stimulates cellular signal transduction. Further studies employing this experimental animal model of acute and chronic relapsing arthritis have shown a beneficial effect when a B2 receptor antagonist was administered to the rats. Interestingly, a deleterious effect was noticed when either therapy with B1 receptor antagonist or a combined B1-B2 receptor antagonist was used. In a similar model of Crohn's disease, P8720 inhibited both acute and chronic gross and histological features including edema, granuloma formation as well as the systemic manifestation of splenomegaly, leukocytosis, anemia and the acute phase reaction.

KLEBSIELLA, INFECTION AND IMMUNITY

David C Straus, Department of Microbiology and Immunology, Texas Tech University Health Sciences Center, Lubbock, Texas, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The most common members of the genus *Klebsiella* are *K. pneumoniae*, *K. planticola*, *K. oxytoca*, *K. terrigena* and *Klebsiella* group 47. Two former species, *K. ozaenae* and *K. rhinoscleromatis* are now considered to be biochemically inactive strains of *K. pneumoniae*. Of these, the most commonly isolated pathogen is *K. pneumoniae*, also known as Friedlander's bacillus. As its name implies, it is usually isolated from cases of pneumonia, but it can infect other parts of the body, such as the urinary tract and wounds. Because of its overwhelming importance, this entry will deal exclusively with *K. pneumoniae*.

Characteristics of the organism and its antigens

K. pneumoniae grows as lactose-fermenting colonies on differential enteric isolation media. It is non-motile, i.e. it does not produce flagellar (H) antigens. Encapsulated *K. pneumoniae* appear quite opaque and mucoid when growing on laboratory agar. These organisms are virulent in humans and animal models. Avirulent *K. pneumoniae* (those which produce no capsules) appear smaller and translucent on similar agar surfaces. *K. pneumoniae* produces both O (somatic) and K (capsular) antigens. The term K antigen comes from the German, *Kapsule*, and was first used to describe the polysaccharide antigens of enteric bacilli. The O antigen is a polymer of repeating oligosaccharide units of several monosaccharides. There are at least eight different O antigen types. The K or capsular antigen of *K. pneumoniae* can be seen by employing the India ink stain, which is comprised primarily of carbon particles. These polysaccharide antigens are used primarily for serotyping. There are at least 77 known antigens. Epidemiologic studies have demonstrated a predominance of certain serotypes in human infections.

Immune responses of the host

In healthy adults, natural host resistance against *K. pneumoniae* is quite high. The progression of this disease and its prognosis are primarily related to age and its predisposing factors. Accordingly, the typical patient is a middle-aged or older man with underlying medical problems, which can include diabetes mellitus, alcoholism or chronic bronchopulmonary disease. Several animal models have been developed,

including rats, mice and monkeys. Classically, the histopathological features of a *K. pneumoniae* lung infection in humans include a massive confluent lobar consolidation consisting primarily of polymorphonuclear leukocytes, a voluminous edema and abscess formation with massive cavitation. Spontaneous recovery is dependent upon the production of type-specific antibodies to the carbohydrate capsule. These antibodies are usually demonstrable in the serum about 1–2 weeks after initiation of the infection. The primary function of these antibodies is opsonization, as *K. pneumoniae* is rapidly killed by phagocytic cells. Type-specific immunity to *K. pneumoniae* infections is long-lasting. Recurrent attacks of *K. pneumoniae* are usually caused by organisms of a different serotype.

The possibility that *K. pneumoniae* is involved in the development of ankylosing spondylitis (AS) is suggested by the demonstration, in AS patients with active disease, of an increased fecal carriage of *K. pneumoniae* as well as the presence of high levels of serum IgA antibodies against *K. pneumoniae*. The etiology of AS apparently involves some genetic predisposition. The disease occurs mostly in males and many AS sufferers possess the HLA-B27 antigen. However, the correlation with known genetic factors is not absolute. Two main theories have been proposed to explain the association of *Klebsiella* with AS. The molecular mimicry hypothesis suggests that HLA-B27 (expressed in approximately 95% of AS patients) cross-reacts with *Klebsiella* and that antibody produced by the patient against these cross-reactive antigen sites will also bind to self epitopes and produce destructive immunity. The second theory states that a *Klebsiella* plasmid encodes the production of a bacterial modifying factor that reacts with HLA-B27, making it susceptible to immunological attacks. Recently, significantly elevated frequencies and titers of antibodies to *K. pneumoniae* capsular types 26, 36 and 50 were detected in sera from AS patients. These results suggest the predominance of *Klebsiella* serotypes 26, 36 and 50 in patients with AS.

Evasive strategies by the organism

The primary virulence factor of *K. pneumoniae* is its carbohydrate capsule (Figure 1). The capsule allows the organism to resist phagocytosis, and hence death

Figure 1 Electron micrograph of *K. pneumoniae* serotype 1. The bacterium is surrounded by the antiphagocytic carbohydrate capsule (arrows). Original magnification $\times 25\,000$.

in professional phagocytes. Encapsulated strains have been shown to be many fold more virulent than nonencapsulated *Klebsiella* in a variety of different animal models. There have been reports of several toxins produced by *K. pneumoniae*, including enterotoxins, by a number of strains isolated from patients with tropical sprue. However, none of these toxins could account for the extensive lung destruction seen in lobar pneumonia produced by *K. pneumoniae*. Probably the best candidate for this devastating pathological effect is the endotoxin produced by this organism. Indeed, a compound referred to as the extracellular toxic complex (ETC) has been described for *K. pneumoniae*. This material is composed of endotoxin, capsule and protein, and the endotoxin portion was shown to contain the toxic moiety. This material was lethal when injected intraperitoneally into mice, and when it was introduced into the lungs of mice, the pathology seen after 24, 48 and 72 hours was similar to the damage caused by an active *K. pneumoniae* lobar pneumonia. All *K. pneumoniae* serotypes examined to date produce the ETC.

Vaccines

Clinical isolates of *K. pneumoniae* express a number of virulence factors, each with the potential to serve as protective antigens in a vaccine. These factors include the capsular polysaccharide (CPS), pili, endotoxin and outer membrane proteins. Of these virulence factors, only the possession of a well-defined capsule seems to be essential for virulence. Therefore, vaccine development for *K. pneumoniae* has emphasized induction of CPS-specific antibody in the host.

It has already been convincingly shown that antibody to CPS is highly effective in preventing experimental *K. pneumoniae* sepsis. The CPS can be obtained from cell-free supernatants by Cetavalon and ethanol precipitation. Trace quantities of endotoxin present in vaccines can be detoxified by 0.1 N NaOH. In clinical trials, vaccinees received 25–50 μg of *K. pneumoniae* CPS. All vaccinees responded with at least a fourfold or greater rise in immunoglobulin G (IgG) and IgM titers. IgG antibody obtained from these individuals was shown to be highly effective in preventing experimental burn wound bacteremia in mice due to the homologous organism. Currently, a polyvalent vaccine containing the CPS from 25 different *K. pneumoniae* serotypes is being tested, with promising results. These findings indicate that a CPS-based vaccine against *K. pneumoniae* is feasible and should be multivalent, eliciting antibodies directed against the 25 serotypes making up 70% of all the bacteremic isolates.

KNOCKOUT, GENETIC

The term 'knockout' or 'gene disruption' denotes a technology to introduce precise genetic lesions into the genome of the mouse and to produce an animal model with a predefined genetic defect.

Previously, the isolation of mutant animal models has been solely dependent on screening spontaneously occurring mutants or on random mutagenesis using carcinogens. Recent ground-breaking advances in mouse genetics, however, have greatly facilitated this process. Today, it is possible to introduce specific defects into any mouse gene and to study the consequence of the alteration *in vivo*. This has been made possible by technological advances in two areas: 1) the ability to introduce defined changes into the mouse genome using homologous recombination, and 2) the capability to reintroduce genetically altered embryonic stem cells into the germline of the mouse, generating mutant mouse strains. In the following, the current status of the knockout technology and its application for studying the immune system will be discussed.

Gene disruption by homologous recombination

Eukaryotic cells have the intrinsic capability to exchange sequences between two homologous duplex molecules of DNA. This so-called homologous recombination event results in a reciprocal exchange of genetic information so that no nucleotides are lost or added to the participating DNA molecules. Homologous recombination not only takes place between homologous chromosomes but also

between chromosomes and extrachromosomal plasmid molecules that have been introduced artificially into the cells. This mechanism can be exploited to insert plasmid molecules (targeting constructs) into cellular genes in order to alter or destroy them (knockout or gene disruption). Because homologous recombination is a rare event and because most cells will integrate the targeting construct at random into their genome, special selection strategies had to be designed to enrich for homologous recombination. The positive/negative selection scheme employed mostly for gene targeting has been developed by Capecchi and coworkers. It results in inactivation of the target gene by integration of a positive selection marker into the gene coding region (Figure 1).

Initially, a targeting construct is assembled that contains part of the target gene, separated by a positive selection marker. Typically, this marker is the neo gene that confers resistance to the aminoglycoside G418 on cells that have taken up the construct. To enrich for integration of the vector into the target gene via homologous recombination, a negative selection step is employed simultaneously, eliminating cell clones that have undergone random integration of the construct. This is achieved by introducing the thymidine kinase gene of herpes simplex virus (HSV-tk) in the targeting vector. HSV-tk converts inactive nucleoside analogues such as 1-[2-deoxy, 2-fluoro- β -D-arabinofuranosyl]-5 iodouracil (FIAU) into chain terminators that are incorporated into the DNA of the target cell and block DNA synthesis. In the vector described in Figure 1, the HSV-tk gene flanks the homologous gene region and is

Figure 1 Generation of a gene targeting construct. The gene targeting construct is assembled from DNA segments AB and CD, which are derived from the murine target gene locus (wild-type allele). The neo expression cassette is inserted between fragments AB and CD, disrupting essential exon sequences of the target gene (filled box). The herpes simplex virus thymidine kinase gene (tk) is placed adjacent to the gene homology region. In the event of homologous recombination between targeting construct and wild-type allele, the tk gene will be lost but integration of the neo cassette into the target gene will destroy the gene coding sequences (disrupted allele).

Figure 2 Derivation of mice carrying a gene disruption. The targeting construct is introduced into embryonic stem (ES) cell cultures and individual cells carrying the disrupted target gene are isolated by positive/negative selection using G⁴¹⁸ and FIAU. After propagation, the ES cells are injected into mouse blastocysts, which are transferred into pseudopregnant recipient mice for generation of chimeric offspring. Chimeras are crossed with wild-type mice and animals of the F1 generation are tested for the gene defect, transmitted through the germline of the chimeras.

Figure 3 Site-specific recombination by Cre recombinase. Cre recombinase performs site-specific recombination on two loxP sites introduced in tandem into the target DNA. As a result, DNA sequences located between the two loxP sites will be excised from the target DNA and released in the form of a circularized excision product.

lost, when the plasmid is integrated by homologous recombination. In contrast, random integration will frequently result in insertion of the HSV-tk gene into the host cell DNA. These cell clones will be eliminated by selection in FIAU. Using this positive/negative selection strategy, targeting constructs can be introduced into any gene for which homologous DNA sequences are available. Typically, a knockout experiment will generate cells that carry one wild-type and one mutant allele of the target gene.

Generation of mice from genetically modified embryonic stem cells

The capability to introduce genetic modifications such as gene disruptions into mice is based on initial studies by Mintz, extended by Evans and Kaufmann and Martin. Their studies demonstrated that embryonic stem cells (ES cells), derived from the inner cell mass of the early mouse embryos, could be propagated and manipulated in culture without losing their pluripotency. After reintroduction into blastocysts these cells colonized many tissues of the developing embryo including the germline. This offered the

Figure 4 Strategy for Cre recombinase-mediated gene inactivation. A targeting construct is assembled from DNA segments AB, BC and CD of the murine target gene locus (wild-type allele). Essential exon sequences in fragment BC (filled box) are flanked by introns (solid line) containing the neo expression cassette and two loxP sites (arrowheads). Integration of the targeting vector into the wild-type allele does not affect target gene expression because only noncoding intron sequences are modified (floxed allele). However, Cre recombinase activity will cause site-specific excision of exon sequences flanked by the two loxP sites, disrupting the target gene locus (disrupted allele).

Figure 5 Tissue-specific gene disruption in mice. A mouse carrying the floxed target gene in all tissues is bred with an animal expressing the Cre recombinase gene under tissue-specific promoter elements (e.g. T cells). In the offspring, activity of Cre recombinase will disrupt the target gene in T cells exclusively, leaving all other cell types unaffected.

possibility to perform a gene knockout experiment in ES cell cultures and to introduce the genetic alteration into mice by transferring the genetically modified ES cells into mouse embryos (Figure 2).

In detail, ES cell clones heterozygous for a gene disruption are isolated by positive/negative selection and are injected into the blastocoel cavity of mouse embryos at day 3.5 of gestation using micromanipulation. These blastocysts are subsequently transferred into pseudopregnant foster mothers to develop to term. The chimeric animals obtained are bred to normal mice and their offspring are tested for the presence of the mutant allele that has been transmitted through the germ line. F1 generation animals which are heterozygous for the gene alteration can then be

bred to each other to derive mice homozygous for the mutant allele (Figure 2).

Mouse models for genetic defects of the immune system

The gene knockout technology has been particularly useful to study the function of the immune system. Numerous mouse strains with deficiencies in T cell and B cell function, in cytokines and their receptors or in the development of lymphoid organs have been developed. Analysis of these models not only gave new insights into mechanisms controlling the immune system but also provided valuable animal models of immunologically relevant diseases in

humans such as autoimmunity, immunodeficiency and infections.

Conditional gene disruption, the second generation knockouts

Conventional gene disruption by homologous recombination manifests itself in all cells of an organism and at all stages of ontogenesis. Under certain circumstances however, it might be desirable to induce a gene defect only at distinct stages in development or in a tissue-specific manner. For instance, embryonic lethality caused by disruption of developmentally essential genes precludes the analysis of the gene defects in adult animals. One approach to achieve conditional gene inactivation is based on the activity of the Cre recombinase of the bacteriophage P1, a site-specific recombinase which specifically binds to a 34 bp loxP recognition sequence (Figure 3). If two loxP sites are located in the same orientation on a DNA molecule, Cre recombinase-mediated recombination will result in excision of the intervening DNA region, leaving a single loxP site behind. This system has been adapted to achieve inducible gene disruption in mammalian cells.

One such system is described in Figure 4. A targeting construct is generated that contains a region of the target gene modified by integration of the neo marker and one loxP site in one intron and a second loxP site in an adjacent intron. The modified introns flank an essential exon of the target gene. Using standard protocols, this modification is introduced into the target gene of ES cells via homologous recombination (Floxed allele), and mice carrying two copies of the loxP-modified gene are derived (Figure 2). These animals are phenotypically normal as integration of neo and the loxP sites in the intron sequences most likely does not interfere with the functional expression of the gene. However, induced expression of the Cre recombinase in these mice will result in excision of the exon sequences flanked by the two loxP sites and in disruption of the gene (Figure 4, Disrupted allele).

Controlling the temporal and spatial expression of the Cre recombinase in loxP-modified mice is key to determining the conditions of the gene inactivation. Tissue-specific gene inactivation can be achieved by crossing loxP-modified mice with transgenic mice carrying the Cre recombinase gene under the control of tissue-specific promoter elements. In the double transgenic animals, the target gene is inactivated in cell types expressing Cre recombinase but not in other tissues (Figure 5). This approach has been used by Rajewsky and coworkers to inactivate the gene for DNA polymerase β in T cells exclusively, and to

study the importance of the gene product in the somatic gene rearrangements at the T cell receptor gene locus. Previously, these studies have not been possible because the obligate DNA polymerase β gene knockout resulted in embryonic lethality.

L

LANGERHANS CELLS

Andrew Blauvelt, Dermatology Branch, National Cancer Institute, Bethesda, Maryland, USA

Langerhans cells are members of the dendritic cell family and are the major antigen-presenting cells of epidermis. Derived from bone marrow, Langerhans cells or their precursors migrate through blood to the suprabasal area of epidermis, where they represent 2–3% of all epidermal cells. Typical markers for these cells include the cell surface expression of CD1a, a major histocompatibility complex (MHC) class I-like molecule, and the pathognomonic Birbeck granule (Figure 1), a tennis racquet-shaped structure observed on electron microscopy. Functionally, Langerhans cells process epicutaneous protein antigens, migrate from epidermis, and present antigenic peptides to T cells in the context of MHC class I and II molecules, either within skin or within the paracortex region of regional lymph nodes. The study of Langerhans cell function during the sensitization and elicitation phases of contact hypersensitivity has proven to be invaluable as a paradigm for the study of immune responses in general, and for the study of cell-mediated delayed-type hypersensitivity reactions in particular. In addition, the biological effects on Langerhans cell function induced by exogenous agents, such as ultraviolet radiation and the human immunodeficiency virus (HIV), have been intensely studied.

History

In 1868, the German medical student Paul Langerhans described cells in human epidermis that stained with gold chloride and exhibited prominent cell surface processes that resembled neuronal dendrites. Because of the morphologic similarities to neurons, Langerhans believed these cells consisted of primitive

Figure 1 Electron micrograph of a human Langerhans cell demonstrating the classic ultrastructural features of this cell. These include an indented nucleus, a relatively electron lucent cytoplasm, and the pathognomonic Birbeck granules (inset), which are shaped like rods or tennis racquets.

nerve tissue. Others proposed the theory that Langerhans cells represented dying melanocytes being sloughed from the skin surface. In the 1960s, the first description of the characteristic ultrastructural

feature of Langerhans cells (i.e. the Birbeck granule), the observation that the tumors of histiocytosis X contained Langerhans cells, and the demonstration of normal Langerhans cells in murine skin experimentally deprived of neural crest components led to the conclusion that these cells were distinct from neurons and melanocytes. Breakthrough observations that Langerhans cells were bone marrow-derived leukocytes with potent antigen-presenting cell properties followed in the 1970s. Table 1 summarizes the historical highlights in Langerhans cell research prior to 1980. Following the correct characterization and classification of Langerhans cells, recent research has focused on the detailed cellular and molecular mechanisms involved in all aspects of Langerhans cell biology.

Cell surface phenotype and cytokine profile

Langerhans cells are the prototypic nonlymphoid members of the dendritic cell family (Table 2). The cells in this family exhibit prominent dendritic morphology, characteristic phenotype (Table 3), and potent antigen-presenting cell capabilities. These features make this family of cells distinct from monocytes/macrophages and other bone marrow-

Table 1 Historical highlights in the study of Langerhans cells prior to 1980

Year	Significant finding
1868	Cells first described by Langerhans and proposed to represent nervous tissue
1948	Popular theory proposed by Masson that Langerhans cells consisted of dying melanocytes
1961	Birbeck and colleagues describe the characteristic ultrastructural feature of Langerhans cells, the Birbeck granule, which distinguishes them from all other cell types
1962	Langerhans cells first stained for ATPase, defining them further as distinct metabolically active epidermal cells
1965	Basset and colleagues note the cells of histiocytosis X tumors exhibit 'virus-like' particles, which are later noted to be Birbeck granules
1968	Breathnach and coworkers demonstrate Langerhans cells, but not melanocytes and neurons, in mouse skin experimentally deprived of its neural crest component.
1977	Three papers published in a single issue of <i>Nature</i> showing that Langerhans cells express cell surface Fc and C3 receptors, as well as MHC class II molecules, firmly establishing Langerhans cells as immunocompetent cells
1979	Bone marrow origin of Langerhans cells clearly established

Table 2 Selected members of the dendritic cell family and their tissue location

Dendritic cell type	Tissue location
Langerhans cells	Epidermis, oral and genital mucosa ^a
Dermal dendritic cells	Dermis
Veiled cells	Afferent lymph
Interdigitating cells	Paracortex region of lymph nodes (T cell-rich areas) ^b
Blood dendritic cells	Blood

^aThis article focuses on epidermal Langerhans cells, as opposed to mucosal Langerhans cells, although these cells share many of the same features.

^bOf note, follicular dendritic cells found in the cortex region of lymph nodes (B cell-rich areas) are not generally considered to belong to the dendritic cell family.

^cBlood dendritic cells cultured over a 36-hour period as described by Steinman and coworkers.

derived cells. In general, Langerhans cells *in situ* and freshly isolated Langerhans cells represent functionally 'immature' dendritic cells. They express lower levels of cell surface MHC class II molecules and stimulate resting T cells less well in mixed lymphocyte reactions when compared to 'mature' dendritic cells, e.g. peripheral blood dendritic cells. However, upon culturing *in vitro* for 2–3 days, Langerhans cells upregulate MHC class II expression, as well as costimulatory molecules, and become functionally 'mature', i.e. they become potent stimulators in mixed lymphocyte reactions. Table 3 outlines the cell surface antigens expressed by both freshly isolated and cultured Langerhans cells, with a comparison to the antigenic profiles observed on blood dendritic cells and monocytes/macrophages. Of note, cell surface expression of CD1a is a reliable marker for human Langerhans cells (Figure 2); the only other cells that express this MHC class I-like molecule include a subset of cortical thymocytes and a small subset of dermal dendritic cells.

Because of the difficulty in isolating large numbers of relatively pure cells, elucidation of the cytokines produced by Langerhans cells (as well as by other dendritic cells) has been difficult. In particular, the presence of small numbers of contaminating keratinocytes (which produce a wide array of cytokines and growth factors) within selected Langerhans cell populations can confuse this issue. Nevertheless, several investigators have shown that freshly isolated Langerhans cells are capable of producing macrophage inflammatory protein 1 α (MIP-1 α), MIP-2, interleukin 12 (IL-12) and IL-15. In contrast, cultured Langerhans cells produce IL-1 β and IL-6. When carefully controlled for keratinocyte

contamination, it is unclear whether Langerhans cells produce other known cytokines. Interestingly, cytokines produced by surrounding cells (i.e. keratinocytes) can greatly influence Langerhans cell phenotype and function. For example, granulocyte-macrophage colony-stimulating factor (GM-CSF) promotes growth of Langerhans cell precursors and potentiates immune function of Langerhans cells, tumor necrosis factor α (TNF α) promotes viability of Langerhans cells in culture and probably the emigration of Langerhans cells from epidermis, and IL-10 can decrease antigen presentation by Langerhans cells.

Antigen-presenting cell function

Tissue location, dendritic morphology, cell surface phenotype, and ability to migrate to T cell-rich areas make Langerhans cells ideally suited as antigen-presenting cells. Figure 3 outlines the generally accepted model for Langerhans cell-mediated T cell activation. Facilitated by the prominent cell surface dendritic processes, Langerhans cells take up protein antigens or protein-hapten complexes within epidermis. They then traverse the epidermal basement membrane and present MHC-restricted peptides to CD4⁺ or CD8⁺ T cells; antigen presentation occurs either within dermis, to memory T cells that have circulated in dermal capillaries, or within the paracortex area of regional lymph nodes, to naive T cells following Langerhans cells emigration through afferent lymphatics. Evidence to support this model has come from both *in vitro* and *in vivo* studies, and in both human and murine systems. Allergic contact dermatitis (e.g. poison ivy dermatitis) is the prototypic clinical disease associated with sensitization to a contact allergen, Langerhans cell antigen presentation and T cell activation as outlined here.

Not surprisingly, freshly isolated Langerhans cells (analogous to Langerhans cells *in situ*), when compared to cultured Langerhans cells (analogous to Langerhans cells that have emigrated to regional lymph node), are more efficient at antigen uptake *in vitro*. Conversely, stimulation of naive T cells, a process that normally occurs within lymph nodes *in vivo*, is best performed by cultured Langerhans cells *in vitro*. The cell surface antigens present on freshly isolated and cultured Langerhans cells, as outlined in Table 3, are consistent with this functional data. For example, the high levels of cell surface MHC and costimulatory molecules present on cultured Langerhans cells are critical for efficient stimulation of naive T cells. Additionally, Birbeck granules, which are structures that may be involved in antigen uptake, are detected only in freshly isolated Langerhans cells.

Figure 2 Human Langerhans cells within acetone-fixed epidermis stain with FITC-conjugated monoclonal antibody directed against CD1a. To obtain epidermis, a blister was induced on the skin of the volar forearm using vacuum suction and heat and the blister roof (epidermal sheet) was removed using sterile scissors. Note the characteristic prominent dendritic processes.

Figure 3 Schematic diagram showing the function of Langerhans cells in mediating antigen-specific T cell activation. Following contact with an antigen or hapten (which becomes antigenic following binding to a protein carrier) on the skin surface (A), epidermal Langerhans cells take up and process antigen within MHC class I or class II compartments (B). Activated Langerhans cells, i.e. Langerhans cells exposed to antigen, migrate from epidermis and display antigenic peptides on their cell surface (C). For primary immune responses, activated Langerhans cells enter afferent lymphatics within skin and travel to regional lymph nodes (D). To facilitate activation of naive T cells, cell surface MHC and costimulatory molecules are upregulated during this migration. Within the paracortex of lymph node, stimulation of naive T cells occurs in an MHC-restricted antigen-specific manner (E). For secondary immune responses, activated Langerhans cells present antigen and stimulate memory T cells, which circulate in capillaries, within the dermis (F).

Current advances

Exposure to ultraviolet radiation can lead to both local and systemic immunologic defects. In particular, Langerhans cell depletion and dysfunction play a central role in ultraviolet light-induced immunosuppression. Ultraviolet light B (wavelength 290–320 nm) can induce Langerhans cell phenotypic changes and death; it also leads to the repopulation of epidermis with CD36⁺ macrophage-like dendritic cells 24–72 h after exposure. Functionally, the lack of normal Langerhans cells and the presence of abnormal Langerhans cells and macrophage-like cells leads to impaired contact sensitivity. Specifically, application of a contact allergen to ultraviolet light B-irradiated skin can induce tolerance for that particular antigen. In addition, it has been proposed that mice and humans susceptible to the development of skin cancer are those susceptible to ultraviolet light B-induced defects in contact sensitization. These studies suggest that short-term immunologic defects induced by ultraviolet light are linked to long-term defects in processing and presentation of tumor antigens. Thus, in addition to foreign antigen recognition, Langerhans cells are probably important in tumor surveillance within skin.

Epidermal Langerhans cells can be targets for HIV

infection both *in vitro* and *in vivo*, however, most studies show that they do not represent a major reservoir for virus. In contrast, Langerhans cells in genital mucosa (where no stratum corneum exists) may be more easily infected by HIV and therefore may be the first cells infected during initial sexual exposure to HIV. Following emigration to regional lymph nodes, HIV-exposed Langerhans cells may then transmit virus to CD4⁺ T cells. In support of this theory, Langerhans cells and other dendritic cells pulsed with HIV *in vitro* transmit high levels of infection to co-cultured T cells. Interestingly, this efficient transmission of virus does not require dendritic cell infection to occur *per se*. That is, these cells can capture HIV within their prominent cell surface dendritic processes in an infection-independent manner; subsequently, captured virus is transmitted to T cells during the process of antigen-specific T cell activation. Additionally, impaired Langerhans cell function has been proposed as an important factor in the pathogenesis of HIV-associated skin diseases, although initial studies to assess the function of Langerhans cells isolated from skin of HIV-infected individuals failed to detect marked defects in antigen presentation.

LARGE GRANULAR LYMPHOCYTES

Chau-Ching Liu, Department of Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, USA

John Ding-E Young, Laboratory of Cellular Physiology and Immunology, The Rockefeller University, New York, USA

Studies performed in the 1970s on human peripheral blood mononuclear cells led to the identification of a unique population of non-T, non-B cells bearing receptors for the Fc portion of immunoglobulin G. These cells, originally called third population cells or T₃ cells, are now named large granular lymphocytes (LGLs) based on subsequent studies conducted in several laboratories.

Morphology, phenotypic markers, and lineage(s) of large granular lymphocytes

LGLs are morphologically distinctive in having a low nucleus/cytoplasm ratio, with an indented nucleus

and many azurophilic granules in the cytoplasm. These granules can be easily identified under the light microscope using various cytochemical staining techniques (**Figure 1**) and appear opaque (electron-dense) under the electron microscope. LGLs represent a minor population, ranging from 2 to 15%, of human peripheral blood lymphocytes. Similar cell populations have also been found in the blood and different tissues/organs of mice, rats, and other animal species. In rats, the 'pit cells' (so named because of the presence of numerous cytoplasmic granules resembling fruit pits) identified in the liver sinusoids were also found to be LGLs. Owing to their larger size and lower density, LGLs can be readily separated from small ('resting') lymphocytes by centrifug-

Figure 1 LGLs in human peripheral blood and after isolation. The cytoplasmic granules of peripheral blood LGLs (indicated by arrows; top and middle panels) are visualized by cytochemical staining for α -naphthylacetate esterase activity. Small, discrete granules and occasionally giant granules can be identified. May-Grunwald-Giemsa stain of isolated LGLs (bottom panel) show more clearly their indented nucleus and abundant cytoplasm with azyrophilic granules (indicated by a pointer). Magnification $\times 1000$.

ation on discontinuous Percoll density gradients, allowing for their characterization in detail.

The phenotypic markers expressed by LGLs suggest heterogeneity in this population of cells. Most human LGLs express CD2, CD16 (Fc γ RIII), CD56 (NKH1; Leu-19), but not CD3 and T cell receptor (T cell markers) or surface immunoglobulin and CD19 (B cell markers). Some LGLs, however, do express T cell surface molecules such as CD8. On the other hand, some LGLs have been shown to express a myeloid marker protein recognized by a monoclonal antibody OKM1. In mice, most LGLs are of

the CD3⁺CD4⁺CD8⁺ phenotype but express other surface antigens such as NK-1.1/2.1, LGL-1, and asialoGM₁. Some mouse LGLs also express CD8 (Lyt-2) surface marker. The heterogeneity in the phenotypes of LGLs, while posing an ambiguity of their relationship with other hematopoietic cell lineages, indicates the diversity in their precursor cells (see below). However, recent studies have suggested that LGLs are derived from lymphoid progenitor cells in the bone marrow (Figure 2).

Functions

When the cytolytic activities of different populations of peripheral blood lymphocytes separated on Percoll density gradient were investigated, it became evident that LGLs accounted for virtually all of the so-called 'natural' cytotoxicity. Natural cytotoxicity is thought to be mediated by natural killer (NK) cells which, in contrast to cytotoxic T lymphocytes (CTLs), do not exhibit antigen-specific memory upon immunization. NK cells recognize antigens/target cells in a non-major histocompatibility complex (MHC)-restricted manner. They have also been shown to mediate antibody-dependent cellular cytotoxicity (ADCC). Our understanding of how NK cells recognize/interact with target cells has significantly advanced following the identification of several families of NK cell receptors (e.g. Ly-49 in mice) in the past few years. Remarkable progress has also been made in the elucidation of the cytolytic mechanisms utilized by NK cells and CTLs. Studies have revealed the presence of a number of cytolytic mediators in the cytoplasmic granules of NK cells and CTLs.

Due primarily to the functional correlation outlined above, the terms LGL and NK cell are often considered interchangeable. However, it should be pointed out that not all LGLs are NK cells and not all NK cells exhibit the morphology of LGLs. CD3⁺CD8⁺ CTLs, which are small and have little cytoplasm with none or few granules under resting conditions, can develop LGL morphology upon stimulation by antigens and/or cytokines (e.g. interleukin 2, IL-2). For example, it has been clearly demonstrated that LGLs isolated from mice infected with lymphocytic choriomeningitis virus contain both CD3⁺asialoGM₁⁺ NK cells and CD3⁺asialoGM₁⁺ CTLs. Moreover, small agranular NK cells have been reported in the literature. Therefore, LGL morphology may represent an activation status of lymphocytes rather than a unique feature of NK cells. It is now widely accepted that LGLs are the phenotypic expression of a variety of activated cytolytic cell types, which include NK cells, CTLs,

Figure 2 Schematic diagram of the development of LGLs.

and γ/δ T cells. Nevertheless, it should be emphasized that LGLs, regardless of whether they are NK cells, CTLs or γ/δ T cells, are thought to play an important role in immune defense against viral infections or infections with other microbes, as well as in immune surveillance against tumor cells.

In addition to mediating cytolytic activity, LGLs have been shown to secrete a variety of cytokines, such as IL-1, IL-2, interferons, and colony-stimulating factors. These cytokines can stimulate the growth of hematopoietic cells, activate other immune cells, and induce the expression of various genes crucial for immune responses including those encoding MHC. This functional capacity of LGLs indicates their involvement in the regulation of immune responses.

Other laboratory and clinical features

The growth of LGLs appears to be under the regulation of various cytokines, in particular IL-2. Early studies demonstrated that high concentrations of IL-2, in the absence of other stimuli such as antigens or mitogens, can stimulate the proliferation of LGLs but not T lymphocytes. Moreover, LGLs propagated in the presence of IL-2 retain potent cytolytic activity. The capacity of LGLs to respond directly to IL-2 is probably due to the high level of expression of the IL-2 receptor β chain. In addition to IL-2, interferon γ is also capable of stimulating the growth of LGLs. These observations, combined with the fact that LGLs themselves can secrete cytokines, suggest that LGLs are important players in the cytokine network of the immune system.

The remarkable response of LGLs to IL-2 has made it possible to generate lymphokine-activated

killer (LAK) cells *in vitro*. LAK cells, propagated primarily from LGLs/NK cells isolated from peripheral blood, contain more cytoplasmic granules and display a broader range of cytotoxicity against tumor cells than do their precursor LGLs. Similarly, the so-called 'tumor-infiltrating lymphocytes' (TILs), probably of CTL origin and with potent cytolytic activity, can be generated in culture in the presence of IL-2. These mighty killer cells, alone or in conjunction with IL-2, have been used in adoptive immunotherapy of advanced cancer.

Defects in LGL development, growth or functioning may result in clinical disorders. For example, aberrant proliferation of LGLs can lead to LGL leukemia. In addition to the expansion of LGLs, patients with LGL leukemia often develop accompanied abnormalities such as neutropenia (decrease of neutrophils) and rheumatoid arthritis. Hypofunction of LGLs/NK cells has been observed in patients with the Chédiak-Higashi syndrome, a genetic disorder associated with fusion and defective degranulation of lysosomes and cytoplasmic granules in various types of granulated cells. As a consequence of granule dysfunction in hematopoietic cells, these patients exhibit increased susceptibility to infections. In mice, the beige mutation results in a phenotype similar to that of the Chédiak-Higashi syndrome, with anomalies in granule formation in LGLs/NK cells and reduced cytolytic capacity.

LECTINS

Halina Lis and **Nathan Sharon**, The Weizmann Institute of Science, Department of Membrane Research and Biophysics, Rehovot, Israel

Lectins (*L. legere*, to select or choose) are cell-agglutinating proteins of nonimmune origin that bind mono- and oligosaccharides reversibly and with high specificity. They also precipitate polysaccharides and glycoproteins. The agglutinating and precipitating activities of lectins are very similar to those of antibodies. They can likewise be specifically inhibited by low molecular weight compounds (haptens) which, in the case of lectins, are monosaccharides or oligosaccharides. Indeed, many of the methods of lectin research, as well as the applications of these proteins, are based on immunochemical techniques. Lectins, however, differ from antibodies in several respects. For instance, they are produced not only by animals but by essentially all classes of living organisms and by different types of cell, and are structurally diverse. In their structural diversity, lectins are akin to enzymes, but they are devoid of catalytic activity.

Lectins are of major interest since they act as recognition determinants in many biological processes such as clearance of glycoproteins from the circulatory system, adhesion of infectious agents to host cells, recruitment of leukocytes to inflammatory sites and cell–cell interactions in the immune system. Hundreds of lectins have been purified from plants and other sources, mainly by affinity chromatography on immobilized carbohydrates, and have been characterized. Some serve as invaluable carbohydrate specific tools in biological and medical research, and are used clinically as well.

History

The history of lectins is closely interwoven with that of immunology. Shortly after the first reports appeared on the presence of hemagglutinating proteins in plant extracts – ricin in the castor bean (1888) and abrin in extracts of the jequirity bean (1891) – Ehrlich realized that they would be more useful as model antigens than the bacterial toxins, such as that of diphtheria, which were popular research tools at the time. Although Ehrlich's preparations were very crude, he was able to establish with them some of the fundamental principles of immunology, such as the specificity of the immune response and the transfer of immunity from a mother to her offspring via blood during pregnancy, and via milk after birth. By studying the inhibitory effect of ricin antiserum on the agglutinating activity of ricin, he proved that there was a quantitative relationship between the amount of antiserum and the amount of antigen it neutralized, and thus performed the first quantitative determination of an antibody *in vitro*.

In 1908, Landsteiner observed that the hemagglutinating activities of various seed extracts varied when tested with red blood cells from different animals and concluded that the reactions of plant hemagglutinins 'resemble antibody reactions in all essentials'. The sugar specificity of lectins was discovered in 1936 by Sumner who found that hemagglutination by concanavalin A, the jack bean lectin, was inhibited by cane sugar. With much foresight, Sumner suggested that the agglutination might be the

consequence of a reaction of the lectin with carbohydrates on the erythrocyte surface.

In the 1940s, Boyd and Reguera, and independently Renkonen, discovered that certain seeds contain agglutinins specific for some human blood group antigens. Thus, lima bean lectin was found to be specific for A-type erythrocytes and the lectin from the seeds of *Lotus tetragonolobus* specific for O-type cells. Subsequently, lectins specific for other blood groups were found. Blood type-specific lectins played a crucial role in the demonstration, by Kabat and by Watkins and Morgan, that carbohydrates are the immunodeterminants of the ABO blood group system.

Despite these developments, lectins attracted only limited attention until the early 1960s, when Nowell first reported that the lectin of the red kidney bean (*Phaseolus vulgaris*), known as phytohemagglutinin (PHA), is mitogenic. This discovery had a revolutionary impact on immunology in that it shattered the view, held until then, that small, resting lymphocytes are dead-end cells that could neither divide nor differentiate. It led to increased interest of immunologists in lectins. Thus, interleukin 2 was discovered in 1976, by Gallo, in the growth medium of normal human lymphocytes stimulated by PHA. In the late 1970s, Reisner and Sharon introduced the lectins for lymphocyte fractionation and purging of bone marrow for transplantation across histocompatibility barriers. More recently, lectins have been shown to perform key recognition functions in the immune system.

Molecular properties

Lectins constitute a heterogeneous group of oligomeric proteins that vary widely in their molecular properties (Figure 1). Nonetheless, many of them can be grouped into distinct families that share sequence homologies and similar structural properties, and in some cases also in superfamilies. The largest and most thoroughly studied family is that of legume lectins, which includes concanavalin A, PHA, and the lectins from soybean (SBA) and peanut (PNA). Close to 100 such lectins have been purified, the complete sequences of some 40 of which are known. In addition, the three-dimensional structures of close to ten of these lectins, most in complex with their carbohydrate ligand, have been elucidated.

Typically, legume lectins consist of two or four identical, or almost identical, subunits (or protomers) of 25–30 kDa, each of which contains a single carbohydrate-binding site with the same specificity. A prominent exception is PHA, which occurs as a family of five tetrameric proteins with varying proportions of two classes of subunit, E and L, and different biological properties: E₄ (E-PHA) is a potent hemagglutinin. L₄ (L-PHA) has leukoagglutinating activity and is a potent mitogen; intermediate forms (e.g. E₂L₂ or E₃L₁) possess lower levels of the above activities; E₄ and L₄ also differ in their specificity for oligosaccharides. Other families of plant lectins are those of cereals (e.g. wheat germ agglutinin, WGA) and of solanaceous plants (e.g. potato and tomato lectins). Members of these

Figure 1 Schematic representation of the overall structure of lectins from different sources. (A) Part of fimbria of *E. coli*. The fimbriae are an assembly of different types of subunit, only one of which (black) contains a carbohydrate-binding site. (Reproduced with permission from Sharon N and Lis H (1995) *Essays in Biochemistry* 30: 59–75.)

families, too, consist mostly of two identical subunits but differ markedly in other properties from those of the legume lectins.

Animal lectins are frequently composite molecules with a wide range of molecular weights, consisting of multiple types of protein modules or domains, only one of which serves as a carbohydrate-recognition domain (CRD) (Figure 1). Three types of CRDs have been discerned: P-type, S-type and C-type, each of them shares a pattern of invariant and highly conserved amino acid residues at a characteristic spacing. The occurrence of such a domain in a protein provides a novel guideline for the identification and classification of new lectins. The P-type CRD has to date been found only in the mannose-6-phosphate receptors. Proteins containing S-type and C-type CRDs are known as galectins (previously S-lectins) and C-type lectins, respectively. The galectins constitute a family of soluble lectins that bind exclusively β -galactosides, such as lactose ($\text{Gal}\beta(1-4)\text{Glc}$) and *N*-acetyllactosamine ($\text{Gal}\beta(1-4)\text{GlcNAc}$). They have a relatively simple structure (molecular weights between 14 and 35 kDa) and occur predominantly in mammals, but have also been described in other vertebrates. Their three-dimensional structure is similar to that of the legume lectins and they may thus be considered as members of the same superfamily. The C-type lectins include endocytic lectins, collectins and selectins. Each of these families shares a common overall architecture, defined by the nature of their domains. In addition to their CRDs, the collectins, for example, contain a collagen-like region, while the selectins – E-selectin (CD62E), P-selectin (CD62P) and L-selectin (CD62L) – contain an epidermal growth factor-like domain and several short repeating units related to complement-binding protein. The collectins are similar in design to complement protein C1q, which also contains a collagen-like domain linked to globular domains involved in the binding of immunoglobulin.

The sialoadhesins are a family of sialic acid-specific cell surface lectins with variable numbers of extracellular immunoglobulin-like domains and are thus members of the immunoglobulin superfamily. They include the sheep erythrocyte receptor of macrophages (referred to simply as sialoadhesin), CD22 found only on B cells and MAG, the myelin-associated glycoprotein.

Bacterial lectins are usually in the form of fimbriae (or pili), hair-like submicroscopic appendages, consisting of an assembly of 5–6 different types of subunit, only one of which has carbohydrate-binding activity, e.g. for mannose (in type 1 fimbriae) or galactose, $\text{Gal}\alpha(1-4)\text{Gal}$ (in P fimbriae).

Carbohydrate specificity

Lectins are classified into a small number of specificity groups (mannose, galactose, *N*-acetylglucosamine, galactose/*N*-acetylgalactosamine, L-fucose and *N*-acetylneuraminic acid (sugars are of the D-configuration unless otherwise stated)) according to the monosaccharide for which they exhibit the highest affinity. The lectins within each group may differ markedly in their affinity for the specific monosaccharide or its various derivatives. Certain lectins bind monosaccharides poorly, but interact strongly with di-, tri- and tetrasaccharides. Lectins that bind oligosaccharides only include the selectins, specific for the sialylated Lewis^x blood group determinant, $\text{NeuAc}\alpha(2-3)\text{Gal}\beta(1-4)[\text{Fuc}\alpha(1-3)]\text{GlcNAc}$ (SiaLe^x) and its positional isomer, sialylated Lewis^a blood group determinant, $\text{NeuAc}\alpha(2-3)\text{Gal}\beta(1-3)[\text{Fuc}\alpha(1-4)]\text{GlcNAc}$ (SiaLe^a), with both L-fucose and sialic acid required for binding; the sialic acid can be replaced by another negatively charged group such as sulfate. The association constants for the binding of monosaccharides and oligosaccharides to lectins are typically in the range 10^3 – $5 \times 10^4 \text{ M}^{-1}$ and 10^5 – 10^7 M^{-1} respectively. These values are of the same order of magnitude as those for the binding of haptens to antibodies and of substrates to enzymes.

Lectin-carbohydrate interactions

Lectins combine with carbohydrates by a network of hydrogen bonds and hydrophobic interactions; coordination with metal ions may also play a role. In general, the combining sites of lectins within a family are structurally similar, but are quite different in different families. For instance, legume lectins, irrespective of their specificity, bind ligands through a constellation of three invariant combining site residues, an aspartic acid, an asparagine and an aromatic amino acid. In the rat mannose-binding protein, a calcium ion serves as the nucleus of the combining site, forming direct bonds with the carbohydrate. Additional bonds are provided by two glutamic acid and two asparagine residues (Figure 2).

Biological activities

Certain lectins are potent mitogens; PHA and concanavalin A, for example, stimulate T cells, while pokeweed mitogen (PWM) stimulates both T and B cells. The mitogenic lectins are polyclonal activators, in that they activate lymphocytes, including memory-type cells, irrespective of their antigenic specificity. Prior to the advent of monoclonal antibodies to cell surface antigens, lectins were the major tool for

Figure 2 Binding of carbohydrate and Ca^{2+} to the CRD of rat mannose-binding protein. (A) Ribbon representation of the CRD. The β strands are shown as arrows, the α helices as ribbons. (B) Close-up of sugar interacting with CRD. The equatorial 3- and 4-OH groups of the sugar form hydrogen bonds (dotted lines) with two glutamic acid and two asparagine residues, and coordination bonds (dashed lines) with Ca^{2+} . (Reproduced with permission from Weis WI, Drickamer K and Hendrickson WA (1992) *Nature* **360**: 127–134 Copyright 1996 Macmillan Magazines Limited.)

studies of the mechanism of mitogenic stimulation of lymphocytes.

In the presence of a mitogenic lectin, a wide variety of antigenically unrelated target cells are lysed by cytotoxic T lymphocytes, a phenomenon known as lectin-dependent cytotoxicity (in analogy to antigen-dependent cytotoxicity). Another form of lectin-dependent cytotoxicity is the killing of tumor cells by macrophages. This activity resembles that of tumor recognizing antibodies that can induce macrophages to lyse tumors.

Several lectins, e.g. concanavalin A and wheat germ agglutinin, are toxic to mammalian cells in culture and to animals, but their toxicity is at least 1000 times lower than that of ricin and abrin. The cytotoxic properties of such lectins serve for the selection of clones of lectin-resistant cell mutants that are widely employed in studies of the genetics, biosynthesis and function of cell surface carbohydrates.

Functions

The major function of lectins appears to be in cell recognition (Table 1). Considerable evidence for such a role has been obtained for the influenza virus hemagglutinin (a lectin specific for *N*-acetylneuraminic acid) and for bacterial surface lectins (or sugar-specific adhesins) that mediate the binding of the pathogens to host cells, a step essential for the initiation of infection. Inhibitors of bacterial lectins protect animals against experimental infection by the lectin-carrying organisms, providing a basis for the development of antiadhesion therapy of microbial infections. Some bacterial surface lectins may allow the specific binding of the bacteria to human polymorphonuclear cells and human and mouse macrophages in the absence of opsonins, leading to activation of the phagocytes and ingestion and killing of the bacteria; the process has been named lectinophagocytosis, in analogy to opsonophagocytosis. The major receptors for mannose-specific *E. coli* are the leukocyte surface antigens CD11/CD18, which also constitute the receptor CR3 for complement fragment iC3b. The same receptors thus participate in both lectino- and opsonophagocytosis. In invertebrates, it has been postulated that lectins on hemo-cyte membranes are nonself-recognition molecules.

The galectins are believed to function in cell adhesion. These lectins are found both inside the cytoplasm and nucleus of different cells and occasionally also on the cell surface and outside the cell. Their expression is developmentally regulated. The elevated levels of galectins that occur on the surface of metastatic murine and human cancer cells may be responsible for the adhesion of these cells

Table 1 Lectins in cell-cell recognition

Lectin	Role in	Carbohydrate determinant
<i>Microorganisms</i>		
Influenza virus		
Human isolates	Infection	NeuAc α (2-6)Gal
Avian and equine isolates	Infection	NeuAc α (2-3)Gal
Amoeba	Infection	Gal/GalNAc
<i>Bacteria</i>		
<i>E. coli</i> , type 1	Infection	Mannose
<i>E. coli</i> , type P	Infection	Gal α (1-4)Gal
<i>Animals</i>		
Galectins	Cell adhesion (?)	Gal β (1-4)GlcNAc
<i>C-type lectins</i>		
Mannose-binding protein	Host antimicrobial defense	Mannose

<i>Sialoadhesins</i>		
Sialoadhesin	Cell adhesion	NeuAc α (2-3)Gal β (1-3/4)GlcNAc; NeuAc α (2-3)Gal β (1-3)GalNAc
CD22		NeuAc α (2-6)Gal β (1-4)GlcNAc
MAG		NeuAc α (2-6)Gal β (1-3)GalNAc

Sialyl Lewis^x, NeuAc α (2-3)Gal β (1-4)[Fuc α (1-3)] GlcNAc; sialyl Lewis^a, NeuAc α (2-3)Gal β (1-3)[Fuc α (1-4)] GlcNAc.

to target organs, a step necessary for the formation of metastases.

The mannose-6-phosphate receptors are responsible for targeting lysosomal enzymes into lysosomes.

The endocytic lectins, a class of C-type lectins, are membrane-bound receptors with different specificities. They appear to be involved in the clearance of glycoproteins, and possibly also of cells (e.g. aged erythrocytes or bacteria), from the circulation. A prominent representative is the mammalian asialoglycoprotein receptor found on hepatocytes, specific for galactose and *N*-acetylgalactosamine. It mediates clearance from the circulation of glycoproteins with complex oligosaccharide units (e.g. ceruloplasmin and α_1 -acid glycoprotein) from which the terminal sialic acid has been removed, exposing galactose residues. Endocytic lectins also play a role in intracellular sorting and trafficking of glycoproteins and in their delivery to the cell surface. The mannose-specific lectin present on the surface of macrophages has been implicated in nonimmune antimicrobial defense. It binds infectious organisms that expose mannose-containing glycans on their surface, leading to their killing by lectinophagocytosis.

A similar function, albeit by a different mechanism, is performed by the soluble mannose-binding protein (MBP) of mammalian serum and liver, a member of the collectin family of C-lectins. The lec-

tin binds to oligomannosides of yeast and fungi, causing activation of complement in an antibody- and Clq-independent manner and subsequent lysis of the pathogens. It also enhances phagocytosis of the invading organisms by acting as an opsonin. Clinical evidence for its importance has come from the identification of an MBP-deficiency syndrome. It results from a mutation of a single amino acid in the collagen-like domain of the lectin and is associated with recurrent, severe bacterial infections in infants.

Adhesive interactions mediated by surface carbohydrates and selectins, another family of C-type lectins, control leukocyte trafficking to sites of inflammation and the migration (homing) of lymphocytes to specific lymphoid organs. The selectins thus provide the best paradigm for the role of sugar-lectin interactions in biological recognition. They mediate the adhesion of circulating leukocytes to endothelial cells of blood vessels, a prerequisite for the exit of the former cells from the circulation and their migration into tissues. L-Selectin, also known as 'homing receptor', is found on all leukocytes and is involved in the recirculation of lymphocytes, directing them specifically to peripheral lymph nodes. The two other selectins (E-selectin and P-selectin) are expressed on endothelial cells when these cells are activated by inflammatory mediators (e.g. interleukin 2 and tumor necrosis factor) released

from tissue cells in response to, for example, wounding, infection or ischemia.

Selectin-mediated adhesion of leukocytes to activated endothelial cells may lead to their harmful accumulation, causing tissue damage, swelling and pain, for instance the inflammation of rheumatoid arthritis or myocardial injury during reperfusion of an ischemic heart. Prevention of adverse inflammatory reactions by inhibition of leukocyte-endothelium interactions, another potential application of antiadhesion therapy, has become a major aim of many pharmacological industries. As shown in animal models, oligosaccharides recognized by the selectins exert protective effects against experimentally induced lung injury. Application of P-selectin- or L-selectin-specific antibodies, or of the selectin ligand sialyl Le^x, attenuates myocardial necrosis after myocardial ischemia and reperfusion. In addition to their involvement in inflammation, selectins may play a role in the spread of cancer cells from the main tumor throughout the body.

The sialoadhesins have been implicated in cell-cell interactions: sialoadhesin and CD22 in those of the immune system and MAG in the process of myelination.

C-type lectins on the surface of natural killer (NK) cells, e.g. Ly49A, appear to act as mediators of carbohydrate-dependent NK-target cell interactions by binding to class I major histocompatibility complex antigens on the surface of the target cells. Such interactions are crucial for delivery of inhibitory signals linked to the prevention of NK cytolytic activity against normal cells.

Applications

Native lectins are used predominantly for applications that are based on precipitation and agglutination reactions or for mitogenic stimulation (Table 2). For numerous purposes, however, lectin derivatives are required. Thus, lectins derivatized with fluorescent dyes, gold particles or enzymes are employed for detection of glycoconjugates in tissue sections, on cells and subcellular organelles, and in investigations of intracellular pathways of protein glycosylation. Lectin binding has been used to demonstrate that membrane receptors for hormones, growth factors, neurotransmitters and toxins are glycoconjugates. Immobilized lectins, such as those that are covalently bound to Sepharose, are indispensable for the purification and isolation by affinity chromatography of glycoproteins, glycopeptides and oligosaccharides. The HLA antigen from normal human cells was first purified to homogeneity with the aid of concanavalin A-Sepharose; immunoglobulin (IgA1) can be easily distinguished from IgA2 by the use of jacalin, the lectin from the jackfruit, *Artocarpus integrifolia*.

Mouse and human cortical (immature) thymocytes differ markedly from the medullary (mature) ones in their surface carbohydrates, as evidenced by the fact that the former are bound and agglutinated by peanut agglutinin (PNA⁺ cells), whereas the latter are not (PNA⁻). Peanut agglutinin therefore provides easy separation of the individual thymocyte subpopulations and makes it possible to examine *in vitro* the developmental and functional relationship between them.

Table 2 Applications of lectins in immunology

Lectin	Source	Monosaccharide specificity	Main application
Concanavalin A	Jackbean (<i>Canavalia ensiformis</i>)	Mannose	T cell mitogen; separation of membrane glycoproteins
DBA	Horse-grass (<i>Dolichos biflorus</i>)	N-Acetylgalactosamine	Blood typing
LTA	Winged pea (<i>Lotus tetragonolobus</i>)	L-Fucose	Blood typing
Peanut agglutinin	Peanut (<i>Arachis hypogaea</i>)	Galactose	Fractionation of human and mouse thymocytes; detection of polyagglutination
Phytohemagglutinin (PHA)	Kidney bean (<i>Phaseolus vulgaris</i>)	^a	T cell mitogen
Pokeweed mitogen	Pokeweed (<i>Phytolacca americana</i>)	^a	B cell mitogen
Ricin	Castor bean (<i>Ricinus communis</i>)	Galactose	In immunotoxins
Soybean agglutinin	Soybean (<i>Glycine max</i>)	N-Acetylgalactosamine	Purging of human bone marrow for transplantation

^a Inhibited only by oligosaccharides.

Selective agglutination by SBA permits separation of mouse B and T splenocytes. However, the main application of this lectin is for purging human bone marrow for transplantation. It is employed routinely for transplantations into children born with severe combined immune deficiency (SCID) with close to 70% success. SBA purging is also used experimentally in bone marrow transplantation of leukemic patients, alongside other accepted techniques for T cell depletion, such as monoclonal antibodies.

Another clinical application of lectins is in blood typing. Thus, the lectins from *Lotus tetragonolobus* and *Ulex europaeus* are employed for identification of blood type O cells, and for the identification of secretors of blood group substances. The lectin from *Dolichos biflorus* is used to distinguish between A₁ and A₂ subgroups and that from *Vicia graminea*, specific for blood type N, to differentiate between M and N cells. In addition PNA, specific for the T antigen, is employed in the differential diagnosis of 'polyagglutination' or ('polyagglutinability'), a condition accompanying certain bacterial and viral infections, in which human erythrocytes become agglutinable by antibodies normally present in the sera of nearly all adults.

Mitogenic stimulation by lectins provides an easy and simple means to assess the immunocompetence of patients suffering from a diversity of diseases (recently, also in cases of the acquired immune deficiency syndrome (AIDS)), and to monitor the effects of various immunosuppressive and immunotherapeutic manipulations. It has been used to examine the effect of stress, both physical and psychological, on the immune system, e.g. sport, weightlessness in space, bereavement. It is also employed for the preparation of chromosome maps for karyotyping, sex determination and detection of chromosome defects, since chromosomes are easily visualized in the stimulated cells.

Legionella pneumophila is a facultative intracellular pathogen that causes Legionnaires' disease in humans. In nature, this organism is commonly present in aquatic habitats, often growing as an intracellular parasite of free-living protozoa. Occasionally, *L. pneumophila* contaminates water distribution systems, resulting in inoculation of humans by inhalation of infectious aerosols or microaspiration of potable water. In susceptible hosts, a fibrinopurulent pneumonia with infiltration of mononuclear and polymorphonuclear phagocytes develops. The infection is progressive and may be fatal, particularly in immunocompromised hosts.

Although *L. pneumophila* is not an obligate intracellular pathogen, progressive disease occurs only when host mononuclear phagocytic cells (MPCs) are permissive to intracellular replication of the organism. In 1980, Horwitz and colleagues demonstrated that *L. pneumophila* replicates in unactivated human MPCs. Subsequent *in vitro* studies demonstrated that *L. pneumophila* also replicates in unactivated MPCs from other animal species, including guinea pigs, rats, nonhuman primates and A/J mice. These species, like humans, develop replicative *L. pneumophila* infections following experimental inoculation. In contrast, other mouse strains, including BDF1, DBA/2, C3H/HeN, C57B1/6, BALB/c and outbred mice, have nonpermissive MPCs; these animals do not support intrapulmonary growth of *L. pneumophila*. Recently, a single autosomal, dominant gene on murine chromosome 13 (designated Lgn-1) was linked to the permissiveness of murine MPCs for *L. pneumophila* replication.

The primacy of intracellular infection in the development of progressive disease has been confirmed by numerous experiments with *L. pneumophila* mutants that are unable to grow in MPCs *in vitro*. Predictably, these mutant bacteria cannot cause progressive infection in animals. The ability of a susceptible host to survive replicative *L. pneumophila* lung infection is dependent on a complex interaction between host MPCs, cytokines and effector cells which facilitate MPC activation and elimination of the pathogen.

Intracellular infection by *L. pneumophila*

L. pneumophila may be ingested by macrophages without opsonization, although they are ingested much more efficiently after exposure to serum and fixation of complement via the alternate pathway. In either case, the bacteria are able to alter the normal phagocytic pathway, avoid intracellular microbiological mechanisms and establish productive intracellular infection.

The uptake of the bacterium into macrophages often involves a novel mechanism of ingestion known as 'coiling phagocytosis', so named because macrophage pseudopods encircle and eventually spiral around the bacterium several times during engulfment (Figure 1, step 2). In these membrane coils, macrophage surface molecules are selectively sorted so that the nascent phagosomal membrane is different from the plasma membrane from which it was derived. Specifically, major histocompatibility complex (MHC) class I and class II molecules and alkaline phosphatase are excluded during uptake, while the CR3 receptor and 5'-nucleotidase are retained in the coiled phagocytic membranes and subsequently eliminated within an hour following bacterial uptake. Ingestion of *L. pneumophila* by amoebae also has novel ultrastructural features. The bacterium is often engaged at the tip of an extended filipod (Figure 1, step 1) and then retracted toward the body of the cell and engulfed. It is not known whether membrane sorting occurs in protozoa; however, Abu Kuwaik and colleagues demonstrated that uptake by the amoeba, *Hartmannella vermiformis*, is a more prolonged process than macrophage uptake, and it requires new protein synthesis. In addition, virulent and avirulent *L. pneumophila* induce distinct sets of amoebal proteins during ingestion.

Once virulent *L. pneumophila* are ingested by either macrophages or protozoa, the phagosomes evade events that normally follow phagocytosis, and the bacteria-containing endosomes become permissive for bacterial replication. In macrophages, normal acidification of the phagosome is attenuated, and the oxidative burst is minimized. During the first 15–60 minutes after uptake, the bacterial phagosome associates with smooth vesicles (Figure 1, step 3). Later, they make intimate contact first with mito-

Figure 1 Events associated with intracellular infection by *L. pneumophila*. (1) Bacteria make contact with filipodia (in amoebae) or (2) are taken up by coiling phagocytosis (in macrophages). (3) The bacterium is ingested within a phagosome, which associated transiently with mitochondria and smooth vesicles. Some avirulent mutants are directed to the degradative endocytic compartments (Ly, lysosome) (4a), but most virulent bacteria are encircled by rough endoplasmic reticulum at ~4 hours after uptake (4b). (5) Bacteria begin to divide in this endosome 4–8 hours after uptake. They double in 2 hours, and grow to large numbers within the endosome over the next 24–48 hours. (6) When the internal bacterial load becomes very large, the cell is lysed.

chondria and then with rough endoplasmic reticulum (ER). Viable *L. pneumophila*-containing phagosomes were shown by Horwitz to evade fusion with thorium-labeled lysosomes (Figure 1, step 4b). More recent immunofluorescence microscopy studies confirm that the late endosomal and lysosomal proteins CD63, LAMP-1, LAMP-2 and cathepsin D are frequently associated with *L. pneumophila*-containing phagosomes. The mechanisms by which lysosomal fusion is avoided is not known; however, Berger and Isberg have identified and cloned a bacterial gene (designated *dotA*) that is required for this pathologic process.

By 4 hours after ingestion, phagosomes containing live *L. pneumophila* appear studded with ribosomes as a result of the association with the ER. This pathologic process resembles autophagocytosis, a cellular process that occurs in response to limitation of nutrients. During autophagocytosis, host cells demarcate sections of cytoplasm by encirclement with smooth endoplasmic reticulum. Proteins within the encircled area are degraded and recycled to the viable parts of the cell. The notion that the *L. pneumophila*–ER

association might represent a form of autophagocytosis was proposed in 1995 by Swanson and Isberg. These investigators showed that amino acid restriction of host cells increases the association of ingested *L. pneumophila* with the ER and facilitates intracellular bacterial growth. Since *L. pneumophila* utilize amino acids as their primary carbon source, direct stimulation of host cell autophagy may account for the ER association. Autophagocytic degradation may make simple nutrients available to the growing bacteria, or, alternatively, the enzymes or channels contained in the ER may facilitate bacterial nutrition.

Between 4 and 8 hours after ingestion, *L. pneumophila* begin to multiply. By 24 to 48 hours, endosomes packed with bacteria fill the cell. Cell lysis occurs, and the released bacteria can reinitiate infection in a neighbouring cell (Figure 1, steps 5 and 6).

Iron availability limits the intracellular growth of *L. pneumophila*

Like all pathogenic bacteria, *L. pneumophila* must compete successfully with the host for iron in order to grow. Siderophores and high-affinity iron uptake systems have not been identified in *L. pneumophila*. Ordinarily, MPCs acquire iron by receptor-mediated endocytosis of iron-binding proteins (e.g. transferrin and lactoferrin) and store it in the form of intracellular ferritin. *L. pneumophila* cannot use iron bound to these proteins. Therefore, the growth of intracellular *L. pneumophila* depends on the accessibility of iron from a transient, intracellular pool.

Interferon γ (IFN γ), a cytokine produced by several cell types (e.g. natural killer (NK) cells, CD4⁺ and CD8⁺ T cells, Thy-1⁺ CD4⁺CD8⁺ $\alpha\beta$ T cells and Thy-1⁺ CD4⁺CD8⁺ $\gamma\delta$ T cells) inhibits *L. pneumophila* replication within human MPCs. Byrd and Horwitz discovered that IFN γ inhibits *L. pneumophila* growth by limiting the availability of intracellular iron. This cytokine was shown to downregulate expression of transferrin receptors on the MPC cell surface and to decrease the concentration of intracellular ferritin. Most importantly, the IFN γ inhibition of bacterial growth could be completely reversed by the addition of excess, exogenous transferrin iron, suggesting that iron limitation is the main mechanism by which this cytokine inhibits intracellular *L. pneumophila* infection.

Host defense against primary replicative *L. pneumophila* lung infections

Because IFN γ limits growth of *L. pneumophila* within permissive MPCs, the ability of the

susceptible host to survive a primary replicative *L. pneumophila* lung infection is dependent on the induction of an active cellular immune response. The central role of cellular immunity is consistent with the clinical observation that legionellosis is most severe in immunocompromised patients with cellular immune defects. Similarly, in rodent models of legionellosis, administration of immunosuppressive agents (e.g. cyclosporine, corticosteroids) increase the lethality of *L. pneumophila* infections. Likewise, the enhanced natural susceptibility of guinea pigs to *L. pneumophila* infection may be due to the relative unresponsiveness of the lymphocytes and mononuclear cells of this species to the bacteria.

Humoral immunity plays a relatively minor role in resistance to primary *L. pneumophila* infection. Horwitz and colleagues demonstrated that: 1) *L. pneumophila* are completely resistant to killing by human complement even in the presence of high-titer human or rabbit anti-*L. pneumophila* antiserum; 2) *L. pneumophila* are resistant to killing by human phagocytes in presence of high-titer antibody and complement in spite of markedly enhanced phagocytosis; and 3) antibody- and complement-opsonized *L. pneumophila* multiply in monocytes as rapidly as unopsonized bacteria. In addition, immunocompromised humans are susceptible to recurrent replicative *L. pneumophila* lung infections even when specific serum antibody is present. These studies suggest that, in the absence of an active cellular immune response, antibody to *L. pneumophila* is an ineffective host defense against *L. pneumophila*. Specific antibody may even be detrimental, as it facilitates uptake of the bacteria by permissive MPCs. Furthermore, recent *in vivo* studies in our laboratories, using a murine model of Legionnaires' disease, demonstrate that clearance of the bacteria from the lung during a primary replicative infection temporally precedes the peak production of antibody against *L. pneumophila*.

Since IFN γ exerts a bacteriostatic, rather than bactericidal effect on intracellular *L. pneumophila*, it is assumed that additional effector cells or mechanisms are required to facilitate the elimination of these bacteria from the lung. Binding of *L. pneumophila* to MPCs results in the direct induction of other cytokines, including tumor necrosis factor alpha (TNF α), interleukin 1 β (IL-1 β), IL-6, granulocyte-macrophage colony-stimulating factor (GM-CSF) and macrophage inflammatory protein 2 (MIP-2). TNF α inhibits intracellular multiplication of *L. pneumophila* in human MPCs *in vitro*, but it is not known whether this cytokine is bactericidal *in vivo*. *In vitro* studies also demonstrate that IFN γ -stimulated NK cells have enhanced capacity to lyse *L. pneumophila*-

infected MPCs. Similarly, cultured human and murine polymorphonuclear leukocytes (PMNs) stimulated with IFN γ and TNF α , also have enhanced bactericidal activity against *L. pneumophila*. Co-stimulation of murine MPCs with IFN γ and TNF α induces nitric oxide synthetase (mac-iNOS) and the production of reactive nitrogen intermediates including nitric oxide (NO). *In vitro* and *in vivo* studies show that NO restricts growth and facilitates the elimination of *L. pneumophila* from rodent alveolar MPCs by: 1) decreasing the concentration of MPC ferritin; 2) amplifying the inhibitory effect of TNF α ; and 3) reducing bacterial viability by a direct toxic effect. In contrast, IFN γ eliminates *L. pneumophila* from cultured A/J mouse peritoneal macrophages by an NO-independent mechanism. It is not known why the effects of NO differ in murine alveolar and peritoneal MPCs. Likewise, the potential role of NO in resistance to human MPCs remains controversial, due mainly to inconsistent demonstration of NO generation by these cells. It is likely, though, that clearance of *L. pneumophila* depends on activation of NK cells, PMNs or macrophages by IFN γ , TNF α , and/or other cytokines.

The cellular sources of IFN γ during primary replicative *L. pneumophila* lung infection have not been identified. *In vivo* studies of BALB/c mice and *in vitro* studies using human peripheral blood mononuclear cells suggest that cells bearing NK markers are induced to make IFN γ in response to virulent *L. pneumophila*. In the A/J mouse model, where IFN γ is required for bacterial clearance, we found that both T and B lymphocytes are recruited into the lung during primary replicative infection. However, mice depleted of both CD4⁺ and CD8⁺ T cells by monoclonal antibody treatment are able to produce IFN γ in the lung and to resolve primary *L. pneumophila* lung infection as efficiently as normal mice. Flow cytometric analysis of lung homogenates from these depleted animals reveal a small but significant population (8%) of Thy-1⁺ CD4⁺ CD8⁺ cells. These cells, which may be CD4⁺CD8⁺ $\alpha\beta$ T cells, or CD4⁺CD8⁺ $\gamma\delta$ T cells, are potential sources of IFN γ .

IL-12, derived from alveolar MPCs and epithelial cells, induces cellular immunity and augments expression of IFN γ from T cells and NK cells. Systemic administration of IL-12 has been demonstrated to increase host resistance to several pathogens, including *Leishmania major*, *Toxoplasma gondii*, *Listeria monocytogenes*, *Mycobacterium tuberculosis*, *Plasmodium chabaudi* and *Klebsiella pneumoniae*. Our recent studies in A/J mice suggest that IL-12 is rapidly induced in bronchoalveolar lavage fluid following induction of a primary infection and

correlates temporally with induction of IFN γ . The relevance of IL-12 to the control of *L. pneumophila* infection remains to be determined.

Acquired immunity to *L. pneumophila* infection

After resolution of a primary *L. pneumophila* lung infection or vaccination with *L. pneumophila* antigens (e.g. *L. pneumophila* cell membranes or extracellular protease), experimental animals become resistant to rechallenge with the bacteria. Splenocytes derived from guinea pigs or rodents previously infected with *L. pneumophila* undergo blastogenesis following stimulation with *L. pneumophila* antigens, and these animals develop delayed-type, cutaneous hypersensitivity. In human studies, Horwitz and colleagues demonstrated that peripheral mononuclear cells taken from patients convalescing from Legionnaires' disease proliferate in response to *L. pneumophila* and secrete lymphokines which inhibit *L. pneumophila* replication in MPCs derived from a naive host.

The effector cells responsible for resistance to reinfection with *L. pneumophila* have not been definitely identified. We recently demonstrated that resistance to reinfection in the A/J mouse model and showed that it is associated with enhanced recruitment of lymphocytes into the lung. However, depletion of CD4⁺ and/or CD8⁺ T cells in these animals has little effect on this resistance. Therefore, resistance to reinfection appears to depend on effector mechanisms that are largely independent of both CD4⁺ and CD8⁺ T cells.

Studies by Newton and colleagues suggests that T_H1 CD4⁺ T cells may play a key role in the development of acquired immunity in BALB/c mice. In this model, primary lung infection induces resistance to a subsequent lethal bacterial inoculum. Consistent with increased activity of T_H1 CD4⁺ T cells, the acquired resistance is associated with antigen-specific splenocyte proliferation, production of IFN γ , and anti-*L. pneumophila* IgG2a antibodies in the serum. In addition, administration of Δ -9-tetrahydrocannabinol, a compound that disrupts the development of T_H1 responses, renders BALB/c mice susceptible to fatal *L. pneumophila* infections after rechallenge with virulent *L. pneumophila*. Since BALB/c mice are not permissive to the growth of *L. pneumophila*, it is likely that this model reflects protection against the toxic effect of a large bacterial inoculum, rather than growth-limiting immunity. The potential roles of T_H1 versus T_H2 cells in the development of acquired immunity to progressive *L. pneumophila* infection in a permissive host has not been explored.

Similarly, the role of humoral immunity in acquired resistance to *L. pneumophila* in the immunocompetent host is also unclear. Although antibody to *L. pneumophila* plays a minimal role in resistance to primary replicative lung infection, some studies suggest that antibody may assist clearance of the bacteria from the lung during rechallenge. Rolstad and colleagues demonstrated that passive transfer of *L. pneumophila*-specific antibody to naive immunocompetent rats protects against normally lethal inocula of *L. pneumophila*. We demonstrated that *L. pneumophila* opsonized with a monoclonal antibody prior to intratracheal inoculation are cleared more rapidly from the lungs of A/J mice than unopsonized bacteria. Clearance of opsonized *L. pneumophila* is correlated with enhanced phagocytosis by host MPCs. Since IFN γ is rapidly induced in this model, the enhanced clearance may reflect increased phagocytosis by nonpermissive, IFN γ activated MPCs.

Summary

Susceptibility to replicative *L. pneumophila* lung infection is determined by the permissiveness of host MPCs to the intracellular growth of the bacteria. These bacteria grow within macrophages and protozoa by avoiding phagolysosomal fusion and by trafficking to a permissive endosome that associates with the host ER. Intracellular growth is controlled both by genetic factors and by the state of MPC activation. Survival of susceptible hosts after primary replicative *L. pneumophila* infections depends on cellular immune mechanisms, including the release of IFN γ . Acquired immunity to *L. pneumophila* is probably the result of a coordinated response between humoral and cellular immune responses, which facilitates enhanced uptake of the bacteria by activated MPCs.

LEISHMANIASIS

Stephen J McSorley, Institut de Pharmacologie Moléculaire et Cellulaire, Valbonne, France

Foo Y Liew, Department of Immunology, Western Infirmary, Glasgow, UK

Leishmaniasis is a parasitic human infection of global importance for which no reliable vaccine currently exists. Infection can result in the development of different disease states which constitute a spectrum of pathology from cutaneous lesion to fatal visceral infection. Mouse models of infection, which also display a similar spectrum of disease, have allowed a clear understanding of the mechanisms of susceptibility and resistance to this infection, making experimental leishmaniasis the best model system for the examination of T cell subset polarization and its relationship to pathogenesis.

Characteristics of the organism and its antigens

The intracellular protozoan parasites of the genus *Leishmania* cause a range of clinical infections, termed leishmaniasis. With the exception of Oceania,

leishmaniasis occurs in most parts of the world, with around a third of the world population at risk of infection. An incidence of 400 000 new cases per year has been reported and the worldwide prevalence is believed to be around 12 million cases. The clinical diseases caused by the leishmaniases fall into three distinct categories:

1. *Cutaneous leishmaniasis* (CL) is termed 'Old World' or 'New World' according to geographical boundaries and the parasite species involved, although the diseases are essentially the same. A lesion develops in the skin at the site of parasite inoculation; it can take some time to heal and may also allow secondary infection. These lesions are typically resolved but may leave a disfiguring scar. Old World CL is caused by *L. major* or *L. tropica* and is found in the Middle East, Africa and parts of Asia; it is variously referred to as Oriental sore, Baghdad boil, Delhi

sore and Aleppo button. New World CL is found mainly in Central and South America and is known as Chiclero's ulcer or Bay sore (in Belize, Peru and Venezuela), pian bois or forest yaws (in Brazil, Colombia, French Guyana and Suriname) and uta (in Peru). This disease is caused by the species *L. mexicana*, *L. amazonensis* and *L. panamensis* among others.

There is a more severe form of CL – diffuse cutaneous leishmaniasis (DCL) – which can occur as a result of infection with *L. aethiopica* in the Old World and *L. amazonensis*, *L. pifanoi* or *L. mexicana* in the New World. In this disease, the parasite is not contained at the site of inoculation but spreads to other subcutaneous tissues around the body, where it causes extensive swelling.

2. *Mucocutaneous leishmaniasis* (MCL) or espundia is caused by *L. braziliensis* and is due to a reactivation of disease in mucosal tissues some time after primary infection at another site. Oronasal and pharyngeal mucosa can be destroyed in highly disfiguring leprosy-like lesions.
3. *Visceral leishmaniasis* (VL) is also found in the Old World, caused by *L. donovani* or *L. infantum* infection, and in the New World, caused by *L. chagasi*. The clinical disease is referred to as kala-azar (black disease), dum dum fever or ponos and is a result of parasite spread from the initial skin infection to tissue macrophages in visceral sites, such as the liver, spleen and bone marrow. Typical symptoms include fever, malaise, weight loss, coughing and diarrhea, accompanied by anemia, skin darkening, and hepatosplenomegaly. This disease is usually fatal if untreated.

While the clinical forms of leishmaniasis are distinct, the parasite species causing disease are not as absolute as outlined above. There are incidences of visceral disease caused by normally cutaneous species and vice versa. The clinical disease observed after infection is probably determined by an interplay between parasite factors and host immune responsiveness to the organism.

Diagnosis of active leishmaniasis is primarily based upon the culture of parasites from infected tissue, although some immunoassays suitable for field work are being developed, including those using monoclonal antibodies and enzyme-linked immunosorbent assays. A skin test using a killed whole parasite preparation (leishmanin) is used as a presumptive test but is not fully specific, while other DNA-based

techniques are accurate but not suitable for all field use.

Treatment of leishmaniasis is based upon the use of antimony compounds, notably the pentavalent antimonials, sodium stibogluconate and *N*-methylglucamine antimonate. These drugs require daily intramuscular injection, have severe side-effects, and are not always effective, particularly against cutaneous leishmaniasis. Second-line drugs include the antimicrobials, such as amphotericin B, pentamidine, metronidazole and nifurtimox.

Most forms of leishmaniasis are zoonotic and various animals are reservoir hosts for the parasite (Figure 1); these include wild cats, dogs, jackals, foxes, sloths, hyraxes and rodents, depending on the precise geographical location. The parasite is transmitted to the mammalian host by over 50 species of sandfly of the genera *Phlebotomus* (in the Old World) and *Lutzomyia* (New World). The infective, flagellate form of the parasite (promastigote) is injected by the sandfly as it takes a blood meal from the host, whereupon the promastigote rapidly invades tissue macrophages (Figure 2). Inside the macrophage, the parasite transforms to a nonflagellate form (amastigote) that resists microbicidal damage from the macrophage and divides by binary

Figure 1 Transmission cycles of *Leishmania*.

Figure 2 Life cycle of *Leishmania*.

fission before rupturing the cell and invading others. Transmission to another sandfly is achieved with the withdrawal of a blood meal containing free parasites or parasitized macrophages.

In the infected sandfly the amastigote attaches to lectins on epithelial cells of the hindgut and transforms into a noninfectious form of the promastigote, the procyclic promastigote. Here the procyclic parasite matures into the infectious promastigote (metacyclic) by a process, termed metacyclogenesis, that involves alterations to a parasite surface antigen, lipophosphoglycan (LPG), allowing detachment from the gut cells. These parasites are then free to migrate to the sandfly proboscis, ready for transmission to another mammalian host. The life cycle of the parasite within the sandfly can be simulated *in vitro* using cell-free medium, allowing analysis of leishmanial antigens and immune responses after experimental infection.

As mentioned above, alterations to the promastigote surface LPG molecule allow the parasite to complete the life cycle in the sandfly. The LPG molecule has been well characterized. It consists of four defined structural domains: a phosphatidylinositol lipid anchor, a phosphosaccharide core, a number of repeating oligosaccharide units and a short oligosaccharide cap. In addition to its importance in the sandfly, LPG is also likely to be involved in the initial binding and entry of macrophages by the promastigote stage. The major surface glycoprotein on all *leishmania* species is the promastigote surface protease (PSP or gp63). Although the protease activity of gp63 upon a number of molecules, including the T cell surface molecule CD4, has been documented, the natural substrate for this protease is unknown. A

number of other cell surface and cytoplasmic proteins with unknown functions have been described, including the cytoplasmic protein, *Leishmania* homolog of receptor for activated C kinase (LACK), which may form the basis of future vaccination strategies.

Immune response of the host

It is clear from numerous studies that immunity to leishmaniasis, both in human disease and murine experimental infection, is determined by the polarization of CD4⁺ T cell subsets. These divergent T cell responses to infection, clearly seen in different mouse strains, either cure or fail to cure infection with *L. major*. The generation of a T_H2 response to infection in mice, with production of interleukin 4 (IL-4) and IL-10, correlates with susceptibility to disease, while mice which respond with a T_H1 phenotype (interferon γ (IFN γ) and IL-2) resolve lesions and remain refractory to further challenge. The adoptive transfer of T_H1 or T_H2 cell lines or clones has demonstrated the critical importance of these cells with regard to disease outcome.

The susceptible BALB/c mouse strain can be manipulated to cure infection using various immunological interventions, which suggests that overcoming susceptibility may be possible in human infection. Sublethal irradiation, depletion of CD4⁺ cells, neutralizing IL-4 production or injecting mice with the T_H1-stimulating cytokine, IL-12, all confer upon BALB/c mice the ability to control infection. The common factor in these treatments is the downregulation or control of IL-4 production in the susceptible mouse early after infection. IL-4 is necessary at this early stage for the efficient generation of a detrimental T_H2 response to the parasite which will impede the development of a protective T_H1 response via the T_H2 cytokine IL-10 (Figure 3). Indeed, these treatments are ineffective if delayed until later during infection as T_H2 polarization has already occurred by this point. The genetic factors involved in determining early production of IL-4 are unknown and the response to IL-4 early during infection may underlie the nature of susceptibility to disease.

The mechanism by which T_H1 and T_H2 cells exert their protective and nonprotective effects has also been extensively studied. The production of IFN γ is essential for the protective capacity of T_H1 cells, as depletion of this cytokine using monoclonal antibodies exacerbates disease. IFN γ activates macrophages to produce tumor necrosis factor α (TNF α), which synergises with IFN γ to allow killing of resident parasites by the induction of nitric oxide (NO) (Figure 4). The production of NO is catalyzed by the

Figure 3 Induction of T_H2 cells in susceptible mice. APC, antigen-presenting cell. Interrupted arrows indicate inhibition.

inducible enzyme nitric oxide synthase (iNOS), whose expression in tissues correlates with disease cure. Blocking NO production *in vivo*, using the inhibitor L- N^G -monomethylarginine (L-NMMA), renders normally resistant mice susceptible to disease, emphasizing the essential nature of this molecule for parasite killing. Resistant mice deficient in iNOS are highly susceptible to *L. major* infection. This was so despite the presence of enhanced T_H1 responses. IL-4 is known to prevent IFN γ -induced NO synthesis by macrophages, thus allowing the survival of the parasite within the host cell.

While the resolution of infection is determined by $CD4^+$ T cell subsets, it is also evident that $CD8^+$ cells, natural killer (NK) cells and $\gamma\delta$ cells can participate in control of infection, although these clearly play a secondary role to $CD4^+$ cells, as adoptive transfer of $CD4^+$ cells from resistant or susceptible mice is sufficient to reproduce the spectrum of disease phenotype outlined above. $CD8^+$ cells are of importance in the resolution of secondary *L. major* infection, as depletion of these cells causes disease exacerbation when cured mice are rechallenged. Early NK cell production of IFN γ has been demonstrated and may be important in the development of T_H1 cells at this critical stage, although the importance of this in

determining disease phenotype is unclear. An increase in $\gamma\delta$ cell numbers has been recorded in both susceptible and resistant mice following infection with *L. major*, which, if depleted using a monoclonal antibody, resulted in the development of larger lesions and increased parasite numbers. It is clear, therefore, that other cellular responses can function in a protective capacity during infection but the ultimate phenotype of disease cure or susceptibility is determined by the $CD4^+$ compartment. In contrast, humoral antibody does not appear to play a significant role in this disease.

Evasive strategies of the organism

The survival of the amastigote stage of the parasite within the environment of the macrophage phagolysosome suggests the presence of mechanisms to resist the normal proteolytic degradation that occurs there. The LPG molecule on the amastigote surface may provide protection against this environment, as LPG deficient strains of *L. major* are killed within 18 hours after internalization. It has also been suggested that the surface protease, gp63, may cleave harmful proteolytic enzymes present in this vacuole, although this has not been clearly demonstrated.

The amastigote stage of the parasite can also interfere with the antigen-presenting function of the infected macrophages, which may impede the detection and activation of infected cells by a protective immune response. This impaired antigen presentation is not due to an inability to process antigen or the lack of major histocompatibility complex (MHC) class II molecules but may reflect an interruption of class II loading with peptide by the presence of amastigotes.

Figure 4 Nitric oxide mediated parasite killing.

While the outcome of leishmaniasis in humans and

mice is balanced between cure of disease or progressive lesion development, depending upon the immune response, it is also clear that the parasite is able to coexist in the mammalian host for some time without producing any observable clinical disease. In resistant mice which cure cutaneous infection, parasites can be cultured 1 year after the lesions resolve. The incidence of leishmaniasis in individuals infected with the human immunodeficiency virus (HIV) also suggests that, years after successful cure of infection, parasites are still present and can reactivate to cause disease in the face of immunosuppression. Therefore, even in the face of a protective immune response and apparent cure of disease, the parasite has the ability to survive and avoid immune-mediated clearance. The mechanism by which this is accomplished is unclear but may involve the parasitization of cells other than macrophages, such as lymph node dendritic cells, in order to avoid macrophage activation.

Vaccination

Human vaccination against leishmaniasis is feasible, as individuals cured of disease remain resistant to reinfection. Indeed, a form of vaccination against leishmaniasis has existed for centuries. Inhabitants of the Middle East would expose the bottoms of their infants to bites from the sandfly vector in order to produce a lesion in a hidden part of the body and thus avoid a potential disfiguring facial scar from later infection. Parasites taken from human lesions, and latterly from *in vitro* cultures, have similarly been administered. There are a number of problems associated with this method when considering large-scale vaccination. Complications accompanying live vaccinations are numerous and serious: around 2–3% of individuals develop large or nonhealing lesions that require treatment. Even in individuals who do not develop these problems the lesions persist for a minimum of 4–5 months. In addition, vaccination of immunosuppressed individuals by this method may have potentially fatal consequences, and vaccination of those with a tendency to develop dermatological complications may be detrimental as there is a clear relationship between live leishmania vaccination and the recrudescence of latent psoriasis or the appearance of new cases. A further complication is the incidence of secondary infection of the lesion, which, in one study, has been documented to occur in 25% of those vaccinated. Finally, the tendency for live parasites to cause immune suppression can lead to a depressed response to other vaccines, such as the triple diphtheria, pertussis and tetanus vaccine, in children for up to 6 months after administration. Because of these extensive complications,

live vaccination is only considered in highly endemic areas and only as a last resort.

Vaccination using a killed preparation of *Leishmania* has been used in Brazil; however, the incidence of disease dropped in this area during the period after immunization, making evaluation of protective immunity difficult. More recent trials with killed parasites coinjected with live bacille Calmette–Guérin (BCG) resulted in a reduction of established cutaneous lesions, indicating that, with an appropriate adjuvant, protective responses could be generated in humans using a killed vaccine.

The route of vaccination is a further complication that has arisen. In the murine model, intravenous vaccination of killed parasites is superior to subcutaneous inoculation. Furthermore, the injection of killed parasites by the subcutaneous route can block the protective effect of intravenous administration. Vaccine delivery systems, such as attenuated *Salmonella*, that deliver antigen directly to the liver and spleen after oral administration may therefore represent an efficient alternative to intravenous delivery, which would be an obstacle to mass vaccination.

While the results of human vaccination studies have not so far resulted in the production of an effective vaccine, the availability of new leishmanial antigens and the development of vaccine delivery systems suited to the induction of T_{H1} responses suggest that a vaccine may be developed in the future. The recent development of DNA vaccination and the cloning of the antigen p24/LACK, which confers complete protection to BALB/c mice when injected with IL-12, suggests that this antigen may be superior to the previous studies using LPG and gp63 and may lead to an effective vaccine strategy for the future.

LEPTOSPIRA, INFECTION AND IMMUNITY

Russell Bey, Department of Veterinary Pathobiology, College of Veterinary Medicine, University of Minnesota, St Paul, Minnesota, USA

Characteristics of *Leptospira* and its antigens

Leptospirosis is a collective term used to denote all infections of humans and animals by members of the genus *Leptospira*. Leptospire are helical-shaped, thin, flexible, motile spirochetes with semicircular hooked ends (occasionally one or both may be straight). They are 0.1 µm in diameter and 6–20 µm in length and are surrounded by an outer envelope or external sheath which covers the cylindrical body. Two periplasmic flagella are inserted subterminally at opposite ends of the cell, with the free ends overlapping in the center of the cell. The flagella are located between the outer envelope or sheath and the protoplasmic cylinder. Inside the protoplasmic cylinder are the cytoplasmic contents.

Various protective and genus-specific antigens are located in the *Leptospira* outer envelope. Lipopolysaccharide material appears to be an important antigenic component of the outer envelope. Antigenic proteins have been visualized by immunoblotting, although only those proteins whose epitope groups remain recognizable by antibodies are detected. Numerous protein bands are found in the outer envelope or on the surface of intact cells. Major antigenic proteins of 22–26, 31–34, 38, 40–44, 50, 60–64 and 95 kDa are found in the outer envelope. Additionally, antigenic proteins of 18, 24, 35, 42, 66 and 77 kDa vary quantitatively between the serovars studied. *Leptospira interrogans*-specific nonagglutinating, nonopsonic antigen (35 kDa) has also been found in outer envelope preparations, but there is speculation that this may have originated from the inner surface of the outer envelope. A 33 kDa protein found in serovar *grippotyphosa* is presumed to be associated with avirulent cultures, while the 41 and 44 kDa proteins appear to be associated with hamster-virulent isolates. Proteins of molecular

weights 31, 34 and 37 kDa make up the flagella. The heat shock protein (hsp) is 64 kDa and shares common antigenic determinants with a wide variety of bacteria. Seven new proteins were produced by serovar *hardjo* when it was cultivated at 37°C.

Two species of *Leptospira* are recognized on the basis of infectivity of laboratory animals: *Leptospira biflexa*, which comprises the nonpathogenic leptospire commonly found in natural waters, and *Leptospira interrogans*, which includes all the parasitic and pathogenic serovars (serotypes). Typing has traditionally been performed by means of agglutination tests with high-titered antisera. The traditional classification methodologies are being augmented by the use of monoclonal antibodies, and the *interrogans* species is being further subdivided into 'geno-species' by restriction endonuclease analysis and DNA probes. The leptospire genome is approximately 4500 kb, and a circular plasmid of approximately 350 kb has been reported.

Leptospire are aerobic and most are readily cultivated in artificial media containing 10% rabbit serum or 1% bovine serum albumin plus long-chain fatty acids (Tween 80) supplemented with ammonium chloride, ferric sulfate, calcium, magnesium, zinc, thiamine and cyanocobalamin. Optimum cultivation temperature is 30°C at a pH of 7.2–7.5. The optimum incubation time for growth ranges from a few days to 4 or more weeks. Fresh isolates tend to require longer incubation. Generally maximum cell densities are attained in 4–10 days, depending on the inoculum and organism being cultivated. Leptospire are visualized by dark-field or phase-contrast microscopy.

Leptospirosis is a zoonosis of worldwide distribution, affecting a wide variety of domestic and wild mammals. Many serovars occur, predominantly in select animal hosts, but distribution of these serovars

occurs readily. One mammalian species may be the primary reservoir for several different serovars. Parasitic leptospires often reside in the mammalian nephritic tubule, from which they are shed into the urine. The duration and intensity of shedding is often dependent on the host and infecting serovar. Following infection, rodents may shed high numbers of some *Leptospira* serovars for the remainder of their life, while shedding other serovars for a relatively short period of time. Domestic mammals generally shed leptospires for several months, with decreasing intensity up to 6 months.

Infections occur as a result of direct contact with the urine of chronically infected animals or indirectly by contact with the *Leptospira*-contaminated water (streams or ponds) or moist soil. Pathogenic leptospires are able to survive more than 3 months in neutral or slightly alkaline soil or water. Animals and humans acquire leptospires either by direct contact with urine or tissues from an infected animal or indirectly by contact with *Leptospira*-contaminated soil or water. Once the host is exposed, leptospires may enter through mucous membranes of the eye, nose, mouth, genital tract or abraded skin.

Most human cases of leptospirosis occur in young adult men, with a peak incidence of summer and early fall. Indirect contact with an infected animal via contaminated water or soil is a very common cause of human infection other than those individuals whose occupation (veterinarian, abattoir workers, dairy farmers, etc.) places them in direct contact with numerous animals. However, the hazards of swimming in ponds or streams frequented by livestock has been demonstrated repeatedly. In the human, disease transmission generally ends, as human-to-human transmission is very rare, only occurring via transplacental infection of the fetus. Worldwide, rodents are the most common source of human infection. In the USA the most common source of human infection is dogs, livestock, rodents and wild mammals. The most common serovars infecting humans are *canicola*, *pomona*, *ballum*, *icterohaemorrhagiae*, *grippotyphosa*, *australis* and *hebdomidis*.

Domestic animals generally become infected in a manner similar to humans, i.e. via contact with *Leptospira*-contaminated urine, water (used by livestock for drinking), soil, infected tissues or uterine discharge. Leptospires have been demonstrated in semen from cattle and pigs and may be transmitted by natural and artificial insemination. Leptospires have been isolated from cows' milk, however natural transmission via this medium has never been demonstrated.

Pathogenicity

Human leptospirosis is primarily associated with occupational exposure, although the number of cases associated with recreational exposure will probably increase. Once entry is gained, there is immediate spread throughout the body without a significant inflammatory reaction. During this incubation phase, which generally ranges from 10 to 14 days but may be as short as 3 or as long as 30 days or more, leptospires are multiplying in the host. Based on findings in experimental animals, multiplication takes place in the liver and blood. Disease onset is often abrupt. Severe headache and muscle tenderness is common and accompanied by an elevation of 1–3°C in body temperature. During this acute febrile phase, leptospires may be cultured from blood, cerebrospinal fluid and possibly urine. Leptospires can be isolated from the urine starting at 2 weeks following clinical disease. Other signs which may be present include jaundice, hemorrhage, malaise, nausea and vomiting. The extent and severity of lesions depends on the infecting serovar and size of the infecting dose. Following the first week of disease the fever subsides, although intermittent short febrile periods may occur over the next 2 weeks. Coinciding with the termination of the leptospiremic phase is the appearance of specific antibodies. Following the first week of illness, leptospires were found in the urine and are shed intermittently for the following 3 months and possibly longer.

In animals the disease process may take a more acute form or be subtle and chronic. The clinical signs observed in domestic mammals are dependent upon the age and species of the animal and the infecting serovar. Fever does occur in domestic mammals but often goes undetected. Clinical signs may include hemorrhage in mucous membranes and kidney tissue, jaundice, anemia, meningitis, anorexia and increased thirst. Often the first observed sign of leptospirosis in animals is abortion, which usually occurs in the later stages of gestation. However, abortion can and does occur at any time during gestation. When abortion occurs it is several days to weeks following leptospires in the blood. Abortion has been associated with leptospirosis in cattle, swine, sheep and horses. The fetus becomes infected as a result of leptospire migration from the maternal circulation. Other complications occurring as a result of *Leptospira* infection are infertility and neonatal death as a result of congenital infection.

Chronic *Leptospira* infection may result in degenerative changes in the kidneys and/or eyes. The interstitial nephritis which occurs results in substantial kidney damage. Tissue damage does not always

occur during acute leptospirosis in areas where aggregates of leptospires are found. Virulent leptospires appear to attach preferentially to kidney cell cultures *in vitro* although no tissue cell damage was noted after 24 hours of incubation. However, kidneys may exhibit lesions characteristic of hypersensitivity reactions following *Leptospira* infection.

Eye damage, which may occur as a result of leptospirosis, varies from acute to chronic. Total blindness may occur in the chronic form of the disease. The humor of the eye in the affected host may harbor viable leptospires and high levels of specific antibody. Ocular involvement occurs more frequently following multiple exposures to *Leptospira*, probably resulting from cross-reactions between leptospiral antigens and proteins of the cornea and lens tissues, particularly in horses. This could partially explain why the lesions which occur in the eye have characteristics similar to those resulting from hypersensitivity reactions.

Immunity

Freshly isolated leptospires do not readily react with specific antibody. This may help the leptospire evade the host immune system, allowing for multiplication prior to clinical disease. Once entry of the host is accomplished, *Leptospira* seem to further evade the host's immune systems by becoming sequestered in the renal tubules, uterine lumen, eye or brain.

Specific immunoglobulins being to appear 5–14 days after leptospiemia. Immunoglobulin M (IgM) is the predominant immunoglobulin produced initially. This antibody, along with complement and phagocytic cells, initiates the clearing of leptospires from the host. Detectable levels of IgG, which is opsonizing and neutralizing, appear a short time later in the disease and persist for variable periods of time. The effect of cell-mediated immunity during *Leptospira* infection is probably limited, however this needs further evaluation.

Vaccines manufactured for use in animals consist of chemically inactivated whole leptospire cultures. These vaccines contain sufficient quality and quantity of antigenic material to prevent clinical disease, abortion, and to reduce incidence of renal shedding in the immunized host. The immunity induced is serovar specific, and although some serological cross-reactions occur, protection afforded by these antibodies is nonexistent. To circumvent the limitations of immune specificity, specific preparations from several serovars are mixed to make more broadly protective vaccines.

It is important to use locally prevalent serovars whenever possible. In addition, most vaccines should

be prepared from virulent leptospires which make better immunogens than avirulent organisms, as less antigenic mass is required to induce immunity and prevent renal infection and/or death. A critical aspect of any *Leptospira* vaccine preparation is that the antigens located in the outer envelope retain their natural configuration as much as possible because the outer envelope is the primary site of antibody–complement interaction.

Parenteral administration of a vaccine stimulates the production of specific IgM followed by IgG, as monitored by the microscopic microtiter agglutination test. IgM appears to be more efficient at agglutinating and neutralizing leptospires than IgG; however, both are critical to the rapid removal of leptospires from the infected host. Titers may be detectable for 6 months or more, depending on the serovar.

LEUKEMIA

Dario Campana, Department of Hematology-Oncology, St. Jude Children's Research Hospital, and University of Tennessee College of Medicine, Memphis, Tennessee, USA

Virchow applied the term leukemia (from the Greek λευκός white and αἷμα blood) in the mid-nineteenth century to indicate a disease characterized by fever, bleeding, enlargement of the spleen and lymph nodes, and accompanied by an abnormally high number of white cells in the peripheral blood. Leukemias are clonal expansions of lympho-hematopoietic cells. Generally, acute leukemias present with high numbers of immature lympho-hematopoietic cells ('blasts') in blood and/or in the bone marrow. In chronic leukemias, the bulk of the neoplastic population is represented by mature-looking cells. The incidence of acute and chronic myeloid leukemias and of chronic lymphoid leukemias progressively increases with age. Acute lymphoblastic leukemia, however, occurs more frequently in childhood and accounts for a sharp age peak for leukemia at 3–4 years of age.

Understanding of leukemia cell biology has progressed dramatically during the last two decades. Advances in the immunological characterization of normal and leukemic hematopoietic cells, the unravelling of immunoglobulin (Ig) and T cell receptor (TCR) gene rearrangements, and the molecular characterization of genetic abnormalities underlying leukemogenesis have increased the accuracy of leukemia classification and provided clues about novel therapeutic strategies.

Acute leukemia

Classification

Morphology and cytochemistry Acute leukemias are classified according to the predominant morphology of the malignant cells. One widely used morphologic classification of acute leukemia was devised in the mid-1970s by a group of French, American and British ('FAB') investigators. There are three main FAB subtypes (L1–L3) of acute lymphoblastic leukemia (ALL) and five (M1–M5) of acute myeloid leukemia (AML); the M1–M3 types reflect discrete stages of myeloid differentiation, while M4 and M5 cases have monocytic components. M6 and M7 denote erythroid and megakaryocytic leukemias, respectively. The precision of leukemia classification can be enhanced by investigating the activity of intracellular enzymes (e.g. myeloperoxidase, esterases and phosphatases) and the distribution of phospholipids and glycogen, by using cytochemical stains. Morphological and cytochemical analyses, however, are not sufficient for an accurate classification of all cases of leukemia. Thus, modern diagnostic procedures usually involve immunophenotypic, karyotypic and molecular studies.

Immunophenotype A few monoclonal antibodies have lineage-restricted reactivity and are, therefore,

Table 1 Immunologic classification of acute lymphoblastic leukemia

useful for leukemia classification. These include CD79 for B cells, CD3 for T cells and antimyeloperoxidase for myeloid cells. Diagnostic panels consisting of these and other reagents, such as CD19, CD7, CD13, CD33, antiglycophorin and CD61 unequivocally classify the vast majority of cases of acute leukemia.

Leukemic cells in B-lineage ALL, the most frequent form of ALL, are typically CD19⁺, CD22⁺, CD79⁺ and surface Ig[–] (Table 1). Most cases are CD10⁺ and are termed 'common' ALL, while CD10[–] cases have been called 'null' ALL. 'Common' and 'null' ALL are collectively termed 'early pre-B ALL'. Other molecules often expressed by these cells include CD24, CD34, CD72, HLA-DR and nuclear terminal deoxynucleotidyl transferase (TdT). In 20–30% of B-lineage ALL cases, cells express cytoplasmic mu heavy chains ('pre-B-ALL'; Table 1). The majority of pre-B ALLs are CD10⁺, while about 60% are CD34⁺ and 40% are CD20⁺. Rare cases in which cells express cytoplasmic *and* surface mu heavy chains without kappa or lambda light chains have been called 'transitional pre-B ALL'. In these cases, the surface mu heavy chains are thought to be associated with pseudo light chains. Finally, the blasts in a few (<5%) B-lineage ALL cases express surface IgM and either kappa or lambda light chains ('B-ALL'). Most B-ALLs are the leukemic phase of Burkitt's lymphoma.

In T-ALL, blasts typically express CD3 (in the cytoplasm or on the cell membrane) and CD7 (Table 1). T cell receptor proteins may be found in the cyto-

plasm of T-ALL blasts lacking surface TCR expression. Among other molecules, CD2, CD5, CD6 and nuclear TdT are expressed in >90% of cases while CD1a, CD4, CD8, CD10 and CD21 are expressed less frequently, and HLA-DR is usually negative. Approximately 80% of T-ALL with surface TCR have the $\alpha\beta$ form of the receptor, the remaining cases being TCR- $\gamma\delta$ ⁺.

Malignant cells in AML express myeloperoxidase, CD13 and/or CD33 (Table 2). CD34 expression is more common in cases with less differentiated morphology. HLA-DR antigens are found in most AML cases, but are negative in the majority of cases of promyelocytic leukemia (FAB M3; Table 2). CD117 is also expressed in many AML cases, with the exception of the promyelocytic and the monocytic subtypes. Leukemias whose blasts react with CD14 antibodies usually have monocytic morphology (FAB M4 and M5; Table 2). Monocytic differentiation of AML is also suggested by CD11c, and CD4 expression. These cases are usually CD34[–]. An additional sign of monocytic differentiation is the high membrane expression of Fc receptors. Finally, cases of acute erythroid leukemia can be identified with antibodies to glycophorin A, while cases of acute megakaryocytic leukemia react with CD41b, CD42a and CD61. These subtypes are rare (<1% of acute leukemias).

Cases composed of two separate blast populations expressing either lymphoid or myeloid markers ('mixed leukemias') are extremely rare. The term 'mixed' or 'biphenotypic' leukemia has also been

Table 2 Predominant immunophenotypes according to FAB classification in AML

MPO, myeloperoxidase.

applied to more frequent cases in which blasts simultaneously express 'myeloid'- and 'lymphoid'-associated markers. For example, a proportion of ALL cases express CD13, CD33 and/or CD15. In most of these cases, the expression of an array of lymphoid-associated antigens and the rearrangement of Ig or TCR genes strongly indicate a lymphoid origin. In a proportion of AML cases, blasts may express 'lymphoid-associated' markers, such as TdT, CD7, CD19 and/or CD56. The myeloid affiliation of these cases is usually clear and they rarely represent a diagnostic problem.

A distinct group of cases (1–2% of acute leukemias) are undifferentiated morphologically and cytochemically, and show recurrent phenotypic features such as HLA-DR, TdT and CD34 positivity, and lack of myeloperoxidase, CD13, CD33, CD79, CD22, CD19, CD3, glycophorin and CD61. These cases have been named 'acute undifferentiated leukemia'.

Antigen-receptor gene rearrangements and genotypic abnormalities Virtually all cases of B-lineage ALL have IgH gene rearrangements, while approximately half of the cases also show TCR δ and TCR γ gene rearrangements and one-third TCR β gene rearrangements. Virtually all T-ALL cases have TCR β and TCR γ gene rearrangements, and 70% of cases have

TCR δ gene rearrangements, while IgH genes are rearranged in approximately 15% of cases. Rearrangements of the same genes in B- and T-lineage cells are not always identical. For example, TCR δ genes found in B-lineage ALL usually have short junctional regions (i.e. V δ 2–D δ 3 and D δ 2–D δ 3), in contrast to the dominant V δ 1DJ δ 1. rearrangements in T-ALL. IgH gene rearrangements in B-lineage ALL at diagnosis are often biclonal or oligoclonal. Moreover, investigators have found changes in the pattern of rearrangement at presentation and relapse for both IgH and TCR genes, an important potential pitfall when these genes are used to track residual leukemia (see below). Nevertheless, in the majority of cases, at least one major rearranged IgH, TCR γ or TCR δ allele appears to persist from diagnosis to relapse. Oligoclonality and clonal evolution in IgH genes are often due to disruption in the V–N–D portion, while the D–N–J sequence is left unmodified. Rearrangements of the IgH and/or TCR genes can also occur in approximately 10% of AML.

Some of the most common genotypic abnormalities of acute leukemia are summarized in Table 3. In approximately 25–40% of cases of adult ALL and 3–5% of cases of childhood ALL, leukemic cells have a reciprocal translocation between chromosomes 9q34 and 22q11 (Philadelphia (Ph)-chromosome),

Table 3 Some recurrent genotypic abnormalities in acute leukemia

Disease	Chromosomal abnormality	Molecular abnormality	Frequency (%) ^a

which disrupts the ABL and BCR genes, respectively. Cytogenetically, the Ph-chromosome found in ALL is indistinguishable from that seen in chronic myelogenous leukemia (CML; see below), but they may differ at the molecular level. While the breakpoints on chromosome 22 in CML usually map to the major breakpoint cluster region (M-bcr) of the BCR gene, most Ph-positive ALL patients show a translocation to the minor breakpoint cluster region (m-bcr) of the same gene. About 25% of pre-B ALL have either the balanced form of $t(1;19)(q23;p13)$ or its unbalanced form, $der(19)t(1;19)(q23;p13)$, while most CD10⁺ ALL cases have 11q23 abnormalities and rearrangements of the MLL gene. The TEL and AML1 genes, which are involved in the extremely rare translocation $t(12;21)(p12-13;q22)$, are frequently rearranged in childhood ALL. Cases with TEL-AML1 rearrangements have B-lineage phenotype and account for 25–30% of childhood B-lineage ALL cases. All cases of surface Ig⁺ B-ALL and Burkitt's lymphoma have translocations involving the MYC proto-oncogene on the 8q24 region and the immunoglobulin genes, most commonly the heavy chain gene at 14q32. In T-ALL, nonrandom chromosomal abnormalities include $t(11;14)(p13;q11)$, $t(1;14)(p34;q11)$ and $t(10;14)(q24;q11)$. In addition, 90 kb deletions on chromosome 1p32, affecting the TAL-1 gene, are found in approximately 10–30% of T cell cases.

In AML, the $t(15;17)(q22;q12-21)$ is found in most cases of acute promyelocytic leukemia (FAB M3). The breakpoints of this translocation affect the retinoic acid receptor α gene (RARA) on chromosome 17 and a transcription factor, PML, on chromosome 15. Other molecular abnormalities included the AML1/ETO fusion in the $t(8;21)(q22;q22)$, CBF β -MYH11 in $inv(16)(p13q22)$, DEK-CAN in $t(6;9)(p23;q34)$, and MLL-AF9 in $t(9;11)(p21-22;q23)$.

Biologic indicators of prognosis

Chromosomal abnormalities are strong prognostic indicators in both ALL and AML. In ALL, hyperdiploidy (51–65 chromosomes), detected in approximately a quarter of children with B-lineage ALL but rare in adults, has consistently been associated with favorable outcome in different chemotherapy programs. It appears that hyperdiploid lymphoblasts have a marked propensity to apoptosis, and a higher sensitivity to methotrexate, one of the main components of ALL therapy. Childhood ALL cases with TEL-AML1 rearrangements also have a strikingly good response to chemotherapy. By contrast, $t(9;22)(q34;q11)$ and BCR-ABL rearrangement and 11q23 abnormalities involving the MLL gene are

typically associated with a dismal response to chemotherapy. MLL gene abnormalities are frequent in infant leukemia. AML cases with $t(8;21)(q22;q22)$ often express CD19 and/or CD56 and show a distinctively good response to chemotherapy. Those with $t(15;17)(q22;q11-21)$ abnormality also respond well to therapy, and show a characteristic response to all-*trans*-retinoic acid, which induces the differentiation of the leukemic promyelocytes to more mature forms. By contrast, monosomy 7, 11q23 translocations and $t(6;9)$ are associated with a particularly poor prognosis.

Children with CD10⁺ B-lineage ALL generally fare worse than CD10⁺ cases, an observation that may be explained by the strong association between CD10 negativity and MLL gene abnormalities. By contrast, CD34 expression and lack of CD45 expression have been correlated with favorable treatment outcome in childhood ALL, the latter feature being strongly associated with hyperdiploidy. The prognostic significance of myeloid antigen expression in ALL is controversial. T-ALL is characterized by a high initial leukocyte count at diagnosis, mediastinal masses in one-half of the patients, and a generally poorer prognosis than early pre-B and pre-B types of ALL. However, in multivariate analysis, the effect of T cell phenotype is lost when correction is made for age and leukocyte counts. Subclassifications of T-ALL according to the level of thymic differentiation have generally failed to show relationships with clinical features or treatment outcome. The expression of CD10 in childhood T-ALL has been associated with better clinical outcome, while adults with T-ALL and CD2⁺ blasts appear to have a particularly unfavorable prognosis. In general, immunophenotypic features of AML do not show strong correlations with clinical parameters or treatment outcome. It has, however, been reported that patients whose blasts lack CD15 and/or express CD34 may have a lower complete remission rate. The predictive value of TdT expression is controversial.

Detection of minimal residual disease

Patients with acute leukemia who have achieved clinical remission may still have up to 10^{10} malignant cells (the upper limit of detection by standard morphologic techniques). Postremission therapy is the same for these patients as for those who may have fewer remaining cells, or perhaps no minimal residual disease (MRD). The assumption underlying studies of MRD is that improved assessments of the total body burden of leukemic cells would increase the accuracy of leukemia treatment and advance cure rates.

Sensitive detection of MRD can be approached

with a variety of techniques, including immunophenotyping, and polymerase chain reaction (PCR) amplification of chromosomal breakpoints and antigen-receptor gene rearrangements. MRD detection with immunologic methods exploits the expression of marker combinations that are found on leukemic cells but are not expressed by normal peripheral blood and bone marrow cells. The maximum sensitivity of these methods for detecting MRD is approximately one target cell in 10^4 when flow cytometry is applied. Virtually all cases of T-ALL are amenable to sensitive flow cytometric analysis of MRD, while approximately 40–50% of B-lineage ALL and AML cases express a suitable immunophenotype. In cases of ALL or AML with genetic abnormalities such as those listed in Table 3, PCR can be applied to amplify RNA or DNA sequences unique to the malignant clone. This approach affords the detection of one malignant cell among 10^6 normal cells. PCR amplification of uniquely rearranged Ig and/or TCR gene sequences can also be used for MRD detection. Here, leukemia-specific probes or primers are needed in each case; the sensitivity of this approach ranges from 10^{-3} to 10^{-6} . Prospective studies of MRD with different techniques, currently ongoing, should clarify its clinical significance. In general, the retrospective studies so far reported showed that the absence of detectable leukemic cells does not ensure that a patient has been cured, but their persistence during or off-treatment appears to correlate with occurrence of relapse.

Chronic leukemias

Chronic myelogenous leukemia

Chronic myelogenous leukemia (CML) is a clonal proliferation of hematopoietic precursor cells, with a greatest incidence between 40 and 60 years of age. The t(9;22)(q34;q11), or Philadelphia (Ph)-chromosome, and BCR-ABL rearrangements are characteristic of CML, and occur in all hematopoietic lineages, an indication that the disease originates from a multipotent progenitor cell. Rare cases of CML (<5%) are Ph-negative but in many of these cases (BCR-ABL) rearrangements can be detected with molecular techniques. PCR amplification of BCR-ABL can be used to detect disease recurrence after allogeneic bone marrow transplantation, although positive PCR results have not consistently predicted treatment outcome.

At diagnosis, CML usually features extremely high white blood cell counts (e.g. $>100 \times 10^9/l$); most cells are granulocytes or maturing myeloid forms. This morphologic appearance is typical of the initial phase of the disease ('chronic phase'). However, it is

not stable and invariably transforms into a 'blast crisis', where the bulk of the neoplastic population is represented by immature-looking forms, resembling those seen in acute leukemias. In the majority of patients, these blasts have morphological and phenotypic features identical to those seen in AML, while approximately 30% of cases have lymphoid morphology and B-lineage ALL immunophenotype; T cell blast crises are rare.

Chronic lymphoid leukemias

B-chronic lymphocytic leukemia (B-CLL) is the most common chronic lymphoid leukemia, and accounts for about 30% of all leukemia patients diagnosed in the Western world, but is less frequent in the Orient. B-CLL is a disease of the elderly, unusual under the age of 40. The most consistent chromosomal abnormality is trisomy of the chromosome 12. Patients with a normal karyotype appear to do better than those with chromosomal abnormalities, and multiple chromosomal abnormalities are associated with a more rapid progression of the disease. Leukemic cells in B-CLL and in other B-lineage chronic lymphoid leukemias (i.e. hairy cell leukemia (HCL), and prolymphocytic leukemia (PLL)) typically express CD19, CD79, CD20 and CD37, whereas TdT is absent (Table 4). In B-CLL, the level of Ig expression on the cell membrane is heterogeneous and often weak. Similarly, membrane expression of CD22 may be extremely weak or undetectable. CD23 and CD5 expression are also characteristic of B-CLL while CD25 and CD11c expression together with high-level expression of CD22 are typical of HCL (Table 4). CD5 expression in B-CLL recalls the phenotype of cells found in primary follicles of fetal lymph nodes and spleen, possibly equivalent to murine Ly1⁺ B cells.

Typical cell markers of T cell chronic lymphoid

Table 4 Predominant immunophenotypes of chronic B cell leukemias

Marker	CLL	PLL	HCL
CD19	+	+	+
CD20	+	+	+
CD37	+	+	+
slg	+/–	+	+
CD5	+	–	–
CD11c	–	–	+
CD22	–	+	+ ^a
CD23	+	–	–
CD25	–	–	+
FMC7	–	+	+

^a Typically, high expression.

leukemias are CD2, CD3 and TCR chains. CD3 and TCR molecules often accumulate in the cytoplasm and are weakly expressed on the cell membrane. In addition, natural killer-associated markers such as CD16 and CD57 are usually found in T-CLL. The majority of T-CLL are CD8⁺, CD4⁻ whereas the neoplastic cells in T prolymphocytic leukemia (T-PLL) are commonly CD4⁺, CD8⁻. In T-CLL, CD7 is usually weakly expressed or undetectable and CD25 is absent, while most T-PLL cases are strongly CD7⁺. Adult T cell leukemia/lymphoma (ATLL) is a disease associated with a human retrovirus (HTLV-I) infection and is distributed in geographical clusters in the southern USA, southern Japan and the Caribbean. In ATLL, cells are CD2 and CD3 positive and usually CD4⁺, CD8⁻. Typically, CD25 is strongly expressed.

Advances in therapy

Approximately 70% of children with ALL can be cured with multiagent chemotherapy. Cure rates are much lower (approximately 30%) for adult patients with ALL, and patients with AML of all ages. Chemotherapy of chronic leukemias is generally directed to delay their progression; disease eradication can only be achieved with allogeneic bone marrow transplantation. Current treatment of acute leukemias emphasizes assessment of risk of relapse at the time of diagnosis. Thus, a continuing challenge is how to identify patients who will need more aggressive (and toxic) therapy to prevent relapse. In addition to clinical features, such as patient's age and white blood cell count at diagnosis, several biologic parameters may predict treatment outcome and, therefore, may be useful for risk classification. The use of immunophenotypic and molecular predictors of outcome are promising tools. Moreover, the *in vitro* determination of leukemic cell growth potential, drug sensitivity and expression of molecules associated with drug resistance (e.g. P-glycoprotein, BCL-2) may also prove to be useful. Finally, the ability to detect MRD in patients with acute leukemia would allow more timely, and potentially curative, intervention. Studies of MRD could also be helpful in autologous bone marrow transplantation, where they could provide means of detecting leukemic cells in 'remission' marrows and in peripheral blood autografts.

In parallel to the refinement of conventional therapies, novel antileukemic agents are becoming available. All-*trans*-retinoic acid is widely used in the treatment of promyelocytic leukemia, and interferon α has already produced significant clinical results in CML and HCL. Interleukin 4 has been shown to be

cytotoxic for leukemic lymphoblasts in cases of high-risk ALL and is currently being tested in clinical trials. Toxin-conjugated, human-mouse chimeric and bivalent monoclonal antibodies against various leukemic cell types are being developed and tested in clinical trials for *in vivo* administration.

LEUKEMIA INHIBITORY FACTOR

Gertrud M Hocke, Department of Genetics, University of Erlangen, Erlangen, Germany

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Leukemia inhibitory factor (LIF) is a cytokine with pleiotropic activities. It was originally isolated, purified and cloned on the basis of its differentiation-inducing activity, but was subsequently found to possess a broad spectrum of biological functions (Table 1).

Expression of LIF

The LIF gene is constitutively expressed at low levels in a number of different cell types and the level can be increased by a variety of stimuli, such as lipopolysaccharide (LPS), interleukin 1 α (IL-1 α), transforming growth factor β (TGF β), epidermal growth factor (EGF), tumor necrosis factor α (TNF α), phorbol ester, retinoic acid or infections with cytomegalovirus (CMV).

Structure of LIF

The characterization of the LIF molecule is summarized in Table 2. The structure of murine LIF, as determined by X-ray crystallography, affiliated LIF to the hematopoietic cytokine family. It is composed of an α helix bundle structure, previously observed for several members of this cytokine family. A variant of murine LIF, derived by alternative splicing of signal sequence exons, is targeted to the extracellular matrix.

Table 2 Structural characteristics of LIF

	Mouse	Human
Molecular weight (kDa)	58 000	45 000
Deglycosylated	20 000	20 000
Chromosomal location	11A1–A2	22q12
Genomic structure (kb)	3 exons	3 exons
3' untranslated region	8.7	7.6
mRNA (kb)	3.2	3.2
half-life (min)	4.1	4.1
	30	30

LIF-mediated signal cascades

LIF belongs to the family of IL-6-type cytokines which includes oncostatin M (OSM), ciliary neurotrophic factor (CNTF), interleukin 11 (IL-11), interleukin 6 (IL-6) and cardiotrophin 1 (CT1). These cytokines have diverse and often overlapping effects on a multitude of cell types. The receptors for members of this cytokine family consist of a cytokine-specific ligand-binding chain and the shared gp130 signal transducer chain, which explains the functional redundancy. Downstream of gp130, two signal-transducing pathways have been recognized, the Janus kinase (JAK)/signal transducer and activator of transcription (STAT) and the Ras/mitogen-activated protein kinase (MAPK) pathway. Both pathways are rapidly activated by LIF in various cell types. In addition, the tyrosine kinases Tec, Fes, Btk

Table 1 Synonyms of LIF

Acronym	Name	Defining action
LIF	Leukemia inhibitory factor	Induction of differentiation of M1 myeloid leukemic cells
D-factor	Differentiation-stimulating factor	
DIF	Differentiation-inducing factor	
DIA	Differentiation inhibitory activity	Inhibition of differentiation of embryonal stem cells
DRF	Differentiation-retarding factor	
ESCGF	Embryonal stem cell growth factor	
	ES cell growth factor	
CNDF	Cholinergic neuronal differentiation factor	Induction of cholinergic neuronal differentiation
HILDA	Human interleukin for DA1-1a cells	Stimulation of myeloid DA1-1 α cell proliferation
MLPLI	Melanoma-derived lipoprotein lipase inhibitor	Inhibition of lipoprotein lipase activity
	Lipoprotein lipase inhibitor	
OAF	Osteoclast-activating factor	Stimulation of bone resorption <i>in vitro</i>
HSF-3	Hepatocyte-stimulating factor 3	Stimulation of acute phase protein synthesis

and Hck were shown to be activated by triggering a signal via gp130. Therefore, in addition to the JAK/STAT and Ras/MAPK signal cascades other pathways are activated, and cross-talk between these pathways has been proposed to exist and to enhance, prolong or specify the cytokine signal.

Functions of LIF

Hematopoietic cells

LIF was identified as a factor capable of inducing the terminal differentiation of the murine myeloid leukemic cell line M1 into macrophages. Activation of the transcription factor STAT3 is essential for LIF-induced differentiation of M1 cells. A number of myeloid leukemic cell lines, which were unresponsive to treatment with LIF, expressed various defects in the JAK/STAT signal cascade, suggesting modulations of this pathway to be a crucial step in leukemogenesis. Although LIF expressed pronounced effects on leukemic cells it had no proliferative activity on normal hematopoietic progenitor cells. Mice with targeted disruption of the LIF receptor ligand-binding chain contained a normal hematologic cell compartment. Targeted disruption of the gp130 signal transducer chain led to hematological disorders during embryogenesis, demonstrating a crucial involvement of gp130-mediated signaling. Attempts to maintain or expand primitive hematopoietic stem cells *in vitro* without concomitant loss of their differentiative and proliferative potential *in vivo* were significantly more successful by culturing the cells in the presence of LIF. The effect of LIF on long-term repopulating stem cells resulted from promoting cytokine expression by bone marrow stroma and may thus be an important tool in blood cell transplantation and transfusion medicine.

Acute phase response

The acute phase response is a systemic reaction against infection or tissue injury, which involves fever, leukocytosis, increased vascular permeability and increased serum levels of acute phase proteins. Acute phase proteins are synthesized in the liver in response to increased levels of certain cytokines including IL-1, TNF α and IL-6. LIF can induce the same set of acute phase proteins as IL-6. This is due to the use of the same signal cascade leading to activation of transcription factors of the STAT family, which then bind to specific control regions of various acute phase genes. In addition, LIF stimulates hepatic triglyceride secretion and mediates changes in lipid metabolism that accompany the acute phase response.

The involvement of LIF in postoperative anorexia and in cancer cachexia is likely to be mediated centrally by decreased food uptake and in addition by its influence on lipid metabolism, both leading to loss of body weight.

LIF is a cytokine released at the site of local injuries, where a recruitment of monocytes and polymorphonuclear cells takes place. Supernatants of monocytes treated with LIF had chemotactic activity for neutrophils and monocytes. LIF acts as an endogenous mediator of cutaneous inflammation and is a mediator of (CMV)-induced inflammatory reactions.

Nervous system

LIF/CNTF has been known to switch the pattern of neurotransmitter expression from the noradrenergic to the cholinergic phenotype. Like CNTF, LIF has profound effects on the survival and maintenance of motor neurons. In addition, LIF may be important during cerebral infection and inflammation. Primary astrocyte cultures express LIF mRNA constitutively, and this expression is regulated by proinflammatory and anti-inflammatory stimuli, suggesting that astrocytes may be an important source of LIF during cerebral inflammation and infection. A rapid upregulation of LIF in the nerve segments, produced by Schwann cells subsequent to nerve injuries, leads to the suggestion that LIF acts as a trauma factor in injured peripheral nerves.

Development

LIF is expressed in a menstrual cycle-dependent manner in human endometrium, with maximal values coinciding with the time of implantation. LIF induces the expression of other cytokines to regulate the temporal and spatial production and activity of proteases and protease inhibitors to create a favorable environment for implantation. By increasing the synthesis of fibronectin LIF acts on human trophoblasts and shifts their differentiation towards the anchoring phenotype.

LIF and cancer

A variety of cancer cells have been shown to respond to LIF by stimulation of proliferation using either a paracrine or an autocrine mechanism. In addition, LIF modulates the capacity of tumor cells to adhere to matrix components, a requisite for a metastatic process, suggesting a potential role in the modulation of tumor progression. The levels of soluble LIF produced by various tumor cell clones correlated with their tumorigenicity.

LIF in transgenic mice

LIF expresses pleotropic functions and thus cannot be categorized according to a single major effect. In addition to the above described functions, LIF is involved in effects, such as the maintenance of totipotent embryonal stem cells in culture, proliferation and differentiation of megakaryocyte progenitor cells, stimulation of new bone formation and calcium release from bones. Targeted disruption of the mouse LIF gene resulted in impaired implantation of blastocysts, but failed to lead to severe defects. This finding can be explained by the functional redundancy of IL-6-type cytokines. Targeted disruption of the specific ligand-binding chain for LIF, which is also used by OSM, CNTF and CT-1, resulted in mice expressing placental, skeletal, neural and metabolic defects and led to perinatal death. Mice without a functional gene for gp130, the signal transducer chain used by all members of the IL-6-type family, died shortly after midgestation. Finally, the lack of the main transcription factor STAT3, used by gp130-triggered signal cascades, resulted in very early embryonic death, demonstrating STAT3 to be a common and crucial endpoint of various receptor-mediated signals.

LEUKEMIA VIRUSES

A Burny^{1,2}, F Bex², F Dequiedt¹, E Adam¹, JS Gatot¹, P Kerkhofs³, R Kettmann¹, D Portetelle¹, A Van Den Broeke² and L Willems¹, ¹Gembloux Faculté Universitaire des Sciences Agronomiques, ²University of Brussels and ³National Institute for Veterinary Research, Belgium

Leukemia is a cancer of blood-forming cells. It can be caused by viruses in humans (adult T cell leukemia) as in animals (mice, cats, cattle, birds, etc.). All known leukemia-inducing viruses belong to the subfamily Oncovirinae of the family Retroviridae. Other retroviruses include the lentiviruses, a subfamily of pathogenic slowviruses (the AIDS viruses, for example) and

the spumaviruses or foamy viruses that cause persistent infections without clinical disease.

The oncoviruses (Gr. *onkos*, mass, bulk) include viruses that infect target cells and lead to their transformation; that is, the virus creates a tumor-producing potential in infected cells. Transformation can occur as an acute phenomenon; it then leads to polyclonal

tumors (like myelomonocytosis induced in the chicken by the avian leukemia virus, MC29). When transformation occurs as a chronic phenomenon, it is a very rare event (1 cell out of 10^{10} – 10^{15} for example). Tumors that develop in the animal are mono- or oligoclonal. They derive from a single (or very few) transformed cell(s).

Acutely transforming retroviruses carry *v-onc* sequences derived from the host proto-oncogenes (*c-onc* sequences).

Conditional and nonconditional mutations affecting oncogenic properties of the virus have been mapped to the *onc* sequences. They code for all or part of the transforming protein; they are not involved in virus replication and are, in most cases, devoid of intron sequences. The latter observation suggests that the recombination event that leads to integration of cellular information occurred as a postsplicing event of the RNA transcript. It could be that recombination took place at the reverse transcription step by a copy choice mechanism. As a consequence, the *onc* information replaces information needed for viral replication and all acutely transforming leukemia viruses known today are replication-defective. They need a nondefective helper for propagation and have been considered as laboratory curiosities rather than widespread pathogens. All however, were isolated from the field.

Nonacutely transforming viruses (inducers of leukemia after a long latency period) carry the information necessary for virus replication. Their oncogenicity is due either to their site of integration in the target cell (avian leukosis virus, ALV; Moloney leukemia virus, MoLV) or to the activity of transactivating proteins that strongly activate virus replication but, at the same time, perturb regulatory circuits that control cell division and/or differentiation (human T lymphotropic virus type I; bovine leukemia virus).

The clinical experience in humans and the experimental data obtained in animals indicate that the development of leukemia is a multistep process. One thus expects that oncogene activation via viral infection is only one step in a cascade. In acute transformation, activation of the whole cascade is a short-duration process. In contrast, infection by nonacutely transforming viruses is supposed to only affect minor determinants of the neoplastic process. A long chronic stimulation is required before overt leukemia appears. Moreover, there are grades in the level of oncogenicity achieved by a given transformed cell. Indeed, DNA transfection experiments suggest that some oncogenes are not able to induce complete neoplastic transformation. However, frank oncogenicity can be achieved if two oncogenes are introduced in the same cell, acting in concert, presumably expressing complementary functions.

Viral carcinogenesis studies have amply demon-

strated that mechanisms leading to cancer include the following five processes:

1. Overexpression of a viral *onc* gene.
2. Capture of a proto-oncogene (*c-onc*) in a retroviral vector and appearance of mutations in the captured gene that make it highly oncogenic (*v-onc*).
3. Combination of two cooperating *v-oncs* in the same provirus.
4. Cooperation between a viral protein and activation of a *c-onc*.
5. Reorganization of the cellular transcriptional processes by a viral transactivation protein.

Overexpression of a viral *onc* gene

In this case, *v-onc* and *c-onc* have identical sequences; *v-onc* is overexpressed due to its viral regulatory environment. Examples include insertion of *myc* in the avian leukemia virus MC29, and in the feline leukemia virus. An analogous state of overexpression can be created if a provirus is inserted upstream of *c-onc* and serves as a strong promoter via its 3' LTR (long terminal repeat). Such a situation is known as 'downstream promotion' of expression. Examples of this situation include a majority of lymphomas induced by Moloney murine leukemia virus and a minority of the chicken lymphomas induced by RAV-1 or ALV.

The Rous-associated virus type 1 (RAV-1), a helper virus that does not carry any oncogene, induces overexpression of *myc* and B cell lymphomas in chickens of the SPAFAS genetic background. The same helper promotes high expression of *erbB* and induces erythroblastic leukemia in chickens of the line 15 I. Obviously host-virus interplay is fundamental in the type of neoplasm induced by the incoming virus. In most cases of downstream promotion, the integrated provirus has lost the 5' part of its genome; transcription starts from the 3' LTR and extends over the neighboring proto-oncogene.

A similar case of overexpression occurs when the enhancing provirus gets inserted downstream of the activated *c-onc*, irrespective of the relative orientations of the provirus and the activated gene. This situation is known as 'regional activation' or 'proviral enhancement'. Regional activation can occur through chromosome breaks, translocations, deletions, insertions, amplifications caused by radiation, chemicals, or just by accident. Many examples of this situation have been described in human leukemia.

Capture of a proto-oncogene (*c-onc*) in a retroviral vector and appearance of mutations in the captured gene that make it highly oncogenic (*v-onc*)

Examples are numerous and include the *onc* genes *v-src* (Rous sarcoma virus), *v-myb* (avian myelo-

blastosis virus) and *v-abl* (Abelson murine leukemia virus). Expression of the encoded protein is a prerequisite to transformation of the target cell and maintenance of the transformed state. Animals that carry tumors caused by such viral agents develop antibodies to the *v-onc* protein (even though it derives from a normal cell constituent playing a role in cell proliferation or cell differentiation).

Combination of two cooperating *v-oncs* in the same provirus

The fact that two active oncogenes may cooperate to confer a growth advantage on the transformed cell is illustrated by the genetic structure of three avian acute leukemia viruses: AEV, with *erbA* (*c-erbA* is the receptor for thyroid hormone) and *erbB* (*c-erbB* is the receptor for EGF, epidermal growth factor); E26, with *myb* and *ets* (the functions of *c-myb* and *c-ets* are not well characterized yet); and MH2, with *myc* and *mil* (*mil* is homologous to the oncogene *raf*, found in the murine sarcoma virus 3611). The *myc*, *myb* and *erbB* genes have been identified separately in other viral isolates as the sole transforming gene. In each case, however, the virus with two oncogenes induces a more pronounced or advanced state of transformation than its counterpart with a single oncogene. In fact, refined experimental systems show that the six *v-oncs* – *myc*, *myb*, *mil*, *ets*, *erbA* and *erbB* – are all separately transforming. Their association in a given virus or their coexpression in a single target cell reinforces the transformed state as appreciated by characteristics such as requirement of specialized culture conditions, colony induction in semisolid medium, requirement for complex liquid medium for proliferation of cells explanted from colonies, and degree of spontaneous differentiation within colonies.

Cooperation between a viral protein and activation of a *c-onc*

The viral protein acts as a mitogen The Friend erythroleukemia is induced in mice by a virus complex containing the defective spleen focus-forming virus (SFFV) and a helper murine leukemia virus. The SFFV envelope gene encodes a membrane glycoprotein, gp55. When expressed at the surface of murine erythroblasts, gp55 is highly mitogenic. It has no effect when it has lost its transmembrane anchor. The first consequence of infection is therefore polyclonal erythroblastosis that leads, however, to cell differentiation and recovery unless the helper is present and contributes to the production of more and more virus particles. Among the numerous integration events, one might concern the Spi-1 site (Spi for SFFV provirus integration site; the Spi-1 product is a transcriptional factor), a site linked with immortalization and tumor

onset. Spi-1 is a presumptive oncogene. Enhanced transcription of Spi-1 follows SFFV integration in the vicinity. The Friend erythroleukemia system combines a mitogenic effect mediated via gp55 at the cell membrane and an insertional activation through enhanced transcription of Spi-1.

Overexpression of a growth factor Another model of cooperation between oncogenes uses *myc*-immortalized monocytes. The cells are superinfected *in vitro* with a CSF-1 (colony stimulating factor)-expressing retrovirus. The result is a strong promotion of tumorigenesis. In this simple model, only two oncogenic activations are required for monocyte/macrophage transformation: immortalization of the cells with *c-myc* and deregulation of the CSF-1 gene. However, not all mechanisms that result in loss of CSF-1 dependence lead to full tumorigenicity, suggesting that, *in vivo*, tumorigenesis may involve multiple secondary events including growth factor independence. Analogous experiments have shown that activation of the macrophage colony-stimulating factor (M-CSF) gene is a secondary event leading to the development of tumors in mononuclear phagocytic cells that have first been immortalized with the *v-fms* oncogene. (*fms* is the *v-onc* found in the McDonough strain of feline sarcoma virus; *c-fms* is the receptor for CSF-1).

Transactivation by a viral gene product

The human T-cell leukemia virus system

The human T-cell leukemia virus type I or HTLV-I is a retrovirus associated with the development of adult T-cell leukemia (ATL). ATL is a malignancy of mature CD4⁺ T-lymphocytes which occurs in 0.1 to 1% of seropositive individuals following prolonged periods of HTLV-I infection. HTLV-I infects CD4⁺ lymphocytes and is also able to transform primary lymphocytes in *in vitro* assays. The peripheral blood from patients with ATL contains transformed lymphocytes which derive from a dominant clone as evidenced by the clonal or oligoclonal integration sites of the HTLV-I provirus.

The mechanism of HTLV-I transformation is different from other retroviruses since HTLV-I provirus is not integrated at specific sites in the genome of the transformed lymphocytes and HTLV-I lacks a typical oncogene. However, HTLV-I codes for a transactivator protein, Tax, which is essential for viral gene expression and is also able to transform cells of both lymphoid and non lymphoid origin. The Tax gene has been implicated in HTLV-I induced leukemogenesis because it transactivates cellular genes involved in the control of T-lymphocyte proliferation, including the genes encoding interleukin 2 (IL-2) and its receptor IL-

2R α , GM-CSF, IL-3, IL-4 and IL-6, as well as the proto-oncogenes *c-sis* and *c-fos*. In addition, Tax immortalizes primary lymphocytes, transforms established rat cell lines and immortalizes primary rat fibroblasts in combination with an activated *ras* oncogene. Furthermore, Tax induces mesenchymal tumors in mice transgenic for the Tax gene and a leukemia of large lymphocytes when the Tax transgene is expressed under the control of a T-cell specific promoter.

Tax activates viral and cellular genes by interacting directly or indirectly with cellular transcription factors, including members of the cyclic AMP response element binding protein (ATF/CREB) and the NF- κ B/cRel families, the two related co-activators CBP and p300 as well as the serum response factor. Activation of HTLV-I gene expression involves direct interaction of Tax with specific members of the ATF/CREB family of transcription factors resulting in enhanced binding of these factors to the regulatory element consisting of three repeats of 21 base pairs in the HTLV-I LTR. This transcriptional regulatory complex subsequently recruits additional factors including the CREB binding protein CBP which bridges upstream transcription factors to the basal transcription machinery.

Tax induction of specific cellular genes including IL-2 and IL-2R involves the stimulation of the DNA binding properties of NF- κ B. NF- κ B is constitutively activated in Tax-expressing cells and in HTLV-I infected cells. This constitutive activation is due to Tax-induced lytic breakdown of I κ B- α which sequesters NF- κ B in the cytoplasm in the absence of specific inducers. Degradation of I κ B- α results in translocation of NF- κ B to the nucleus and subsequent activation of gene expression from specific promoters containing NF- κ B binding sites.

In HTLV-I transformed lymphocytes, Tax exhibits a cytoplasmic diffuse distribution in addition to a nuclear punctate distribution. The discrete nuclear structures containing Tax include components of both basal transcription complexes and splicing complexes, the ATF-01 member of the ATF/CREB family of transcription factors, the two subunits of NF- κ B p50 and RelA as well as both related coactivators CBP and p300. They also include mRNA encoded by a gene specifically activated by Tax suggesting that these nuclear structures are critical for Tax transcriptional and transforming activities.

The Bovine Leukemia Virus system

The Bovine Leukemia Virus (BLV) shares structural homologies with HTLV-I. BLV transforms bovine and ovine B lymphocytes and induces monoclonal leukemia/lymphoma (malignant lymphoma) in 100% of infected sheep with an average latency of 30 months. Only a very limited fraction ($\pm 5\%$) of infected cattle develop tumors, but with a very long latency of about

10 years. Tumor cells always harbor BLV proviral sequences. In sheep tumors, BLV proteins are not expressed, but some degree of expression is found in bovine tumors. It was not established, however, whether expression occurred in transformed cells or in non-tumorous cells, infected by the virus and present in the tumor tissue.

No p53 mutations were found in sheep tumor cells, indicating that this rare event is not required to induce full malignancy of the infected cell in sheep. On the contrary, p53 mutations were uncovered in 50% of BLV-induced bovine tumors. It was also observed that the rate of apoptosis is reduced by 50% in PBMCs of BLV(+) animals as compared to controls. This observation remained valid even in animals carrying a disabled, weakly propagating BLV.

The BLV Tax, R₃ and G₄ viral products play a major role in the transformation process of sheep B cells. Tax phosphorylation occurs at serines 106 and 293 and is required for Tax to be transforming. Mutation of these aa residues into Ala abrogates the transforming potential of Tax but maintains its transactivating capacity for the proviral promoter. BLV viruses deleted for R₃ and G₄ are still infectious but propagate very weakly in sheep. Ten animals infected for more than 5 years did not show any sign of tumor development whilst an average latency of 30 months before onset of tumor was observed in wild type BLV-infected sheep.

Such data assign a role to the regulatory genes tax, R₃ and G₄ in the induction of malignant lymphoma by BLV.

Leukemia viruses are examples of biological plasticity. They have been and still are seeding elements for impressive progress in cancer research. Identification of oncogenes has led to the assumption that onset of a tumor results from alterations of growth induced by lesions in the cell signaling system combined with lesions that perturb the biochemistry controlling the self-renewal and/or the differentiation potential of cells. The time sequence of events seems largely irrelevant, one oncogene can be associated with quite different types of tumors in different tissues. There are many ways that lead to a given end – all paths lead to Rome!

LEUKOCYTE ADHESION DEFICIENCY

Amos Etzioni, Department of Pediatrics and Clinical Immunology, Rambam Medical Center, B. Rappaport School of Medicine, Technion, Haifa, Israel

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Studies of genetic deficiency syndromes have provided important insights into the molecular basis and biology of leukocyte emigration. Both animal and human syndromes are well recognized.

Animal models

A spontaneous mutation in the gene encoding the β_2 -integrin has been described both in dogs and cattle. In the cattle model two point mutations were identified within the gene encoding bovine CD18. These animals suffered from recurrent infections and persistent mature neutrophilia associated with poor growth performance. The carrier frequency of the defective gene among Holstein cattle is approximately 15% in bulls and 6% in cows.

Using methods of homologous recombination in embryonic stem (ES) cells, it is possible to generate strains of mice deficient in specific adhesion molecules. A knockout mouse with CD18 deficiency was found to be viable and fertile, with mild granulocytosis. The mutant mice showed an impaired inflammatory response to chemical peritonitis and delayed rejection of cardiac transplants (Table 1).

In another model, ICAM-1-deficient mice were generated. The animals developed normally and had mild granulocytosis. Deficient mice exhibited abnormalities of inflammatory response especially in impaired neutrophil emigration. In addition, leukocytes from these mice provide negligible stimulation for the mixed lymphocyte reaction. In a recent study using the ICAM-1-deficient mice, mutant mice were resistant to the lethal effects of high doses of endotoxin, which correlated with a significant decrease in neutrophil infiltration in the liver. As the production of various inflammatory cytokines is normal in these mice, the protective effects appear to be related to a

diminution in critical leukocyte–endothelial interactions.

Mice lacking P-selectin develop normally. However, they exhibit striking leukocytosis, diminished rolling of leukocytes in mesenteric vessels and delayed recruitment of neutrophils to the peritoneal cavity after experimentally induced peritonitis. Mice deficient in L-selectin initially have normal levels of leukocyte rolling, but show a significant decline in rolling within the first hour. Furthermore, L-selectin knockout mice have a severe reduction in the number of lymphocytes localized in the peripheral lymph nodes. E-Selectin-deficient mice have a milder defect in neutrophil recruitment, and do not have leukocytosis. Administration of P-selectin-specific antibodies to the E-selectin knockout mice completely blocks neutrophil recruitment, suggesting that in this model some redundancy of function may exist between the two endothelial cell selectins.

Human Leukocyte Adhesion Deficiency (LAD) syndromes

The best way to appreciate the *in vivo* importance of the various adhesion molecules is by examining those rare ‘experiments of nature’ where a specific defect in an adhesion molecule exists. Currently two such syndromes have been described. In the first, LAD I, the integrin family is defective, whilst in the second, LAD II, sialyl Lewis^x, the ligand for selectins, is missing (Figure 1).

LAD I

This syndrome was described more than 10 years ago and is clinically characterized by severe life-threatening infections, chronic neutrophilia and impaired wound healing. Delayed separation of the

Table 1 Adhesion molecule knockout mice

Adhesion molecule	Viability	Leukocytosis	Rolling	Migration	Inflammation
ICAM-1	Good	+++	N	NT	Reduced
β_2 -Integrin (partial)	Good	++	N	Decreased	Reduced
E-Selectin	Good	–	NT	N	Normal
P-Selectin	Good	++	Reduced (early)	N	Reduced (1–4 h)
L-Selectin	Normal	–	Reduced (later)	N	Reduced (6–8 h)
VCAM-1	Nonviable				

N, normal; NT, not tested.

Figure 1 The adhesion cascade: defects in LAD I and II.

umbilical cord, chronic gingivoperiodontitis and lack of pus formation complete the clinical picture. The syndrome is a result of a defect in the expression of the β_2 subunit (CD18) of the integrin molecule. Heterogeneous mutations in the common β_2 chain splicing, frameshift, missense, and initiation codon have been demonstrated to be the molecular basis of LAD I. As a consequence, neutrophils are unable to emigrate from the blood vessels to the tissue since adhesion and transmigration are severely impaired. Biopsies from infected lesions in these patients demonstrated inflammatory infiltrates totally devoid of neutrophils. This histopathologic feature is particularly striking considering that marked peripheral granulocytosis (5- to 20-fold higher than normal) is a constant finding. Although neutrophil motility is the major defect, cellular and humoral immune func-

tion can also be abnormal, but its *in vivo* significance is still unclear.

Clinically, LAD I has been divided into two groups: a severe phenotype and a moderate one. In the severe form no expression of CD18 can be demonstrated and the patients will suffer from life-threatening infections and will die early in life if definite therapy is not instituted. In the moderate form some surface expression (around 5%) exists and these patients have fewer serious infections and survive into adulthood. While antibiotics have some beneficial effect, the definite approach to the treatment of the disease is by bone marrow transplantation which was found to be very successful in LAD I. Since the syndrome is a monogenic disorder involving hematopoietic cells, it is obviously an attractive candidate for curative treatment by gene therapy.

LAD II

This new adhesion molecule deficiency, which was described in 1992, is also characterized by recurrent infections, no pus formation, gingivitis, and pronounced neutrophilia. The severity of the infection resembles the moderate form of LAD I (Table 2). The syndrome is also manifested by mental retardation, growth retardation and exhibits the rare Bombay blood group phenotype. LAD II is due to a congenital defect of endogenous fucose metabolism. This results in an inability to synthesize fucosylated carbohydrate molecules, such as sialyl Lewis^x, the ligand for selectins, on the neutrophils. Neutrophils from LAD II patients express normal levels of β_2 -integrins and L-selectin, but lack sLe^x or other fucose-containing surface antigens. Neutrophils from these patients do not bind to E-selectin expressed on cytokine-activated cultured endothelial cells, or to purified E- or P-selectin, and exhibit a marked decrease in migration to skin chambers or a skin window *in vivo*. Nonetheless, under static conditions the cells adhere normally through integrin-ICAM interactions and can also migrate across endothelial monolayers.

Compelling evidence in support of the current paradigm of leukocyte-endothelial interaction was obtained by using intravital microscopy to study neutrophil behavior in cells from LAD I and LAD II patients. Fluorescein labeled cells were observed during interactions with venules in rabbit peritoneum treated with interleukin 1 to induce E-selectin. Neutrophils from LAD I patients showed normal rolling,

but were unable to stick and emigrate upon chemotactic stimulation. Neutrophils from LAD II patients rolled poorly, and failed to stick and emigrate under the shear forces provided by flow. However, when flow was reduced the cells adhered and emigrated in response to a chemoattractant. This study clearly showed that selectin-carbohydrate ligand interaction initiates low-affinity adhesion, and subsequent activation induces engagement of integrins with endothelial immunoglobulin-like ligands promoting firm adhesion and emigration into the tissue.

LEUKOCYTE CULTURE

Alessandra Cesano and **Daniela Santoli**, The Wistar Institute, Philadelphia, Pennsylvania, USA

The last 10–15 years have seen an explosion of new therapeutic approaches, mostly in the oncologic field. The agents developed are blood-derived cells either intrinsically endowed with direct and/or indirect antitumor activity (such as lymphokine-activated killer (LAK) cells, tumor infiltrating lymphocytes (TILs) and dendritic cells (DC)) or developed for hematopoietic cell transplantation purposes (such as CD34⁺ precursors) after high-dose chemo/radiotherapy protocols. These therapies offer promising novel approaches to cancers that have resisted initial treatment protocols as well as treatment opportunities for patients afflicted with the acquired immune deficiency syndrome (AIDS), other immunodeficiencies and genetic disorders. New technologies have therefore needed to be developed for the large-scale expansion of leukocytes to be used as biological therapeutics.

Classically, small- to medium-scale leukocyte cultures (up to 10^9 cells and for research laboratory purposes only) are performed in sterile containers (consisting of polystyrene flasks or Petri dishes) in various commercially available media (the most commonly used for leukocyte cultures being Roswell Park Memorial Institute (RPMI) 1640 and Iscove's modified Dulbecco's medium (IMDM)) supplemented with either heat-inactivated fetal bovine serum (FBS) or human AB serum, antibiotics and, when indicated, specific growth factors (such as granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin 3 (IL-3), IL-2, etc.). All cell manipulations are performed under laminar flow hoods using sterile supplies and the flasks are kept in humidified 37°C incubators with 5–10% CO₂, depending on the type of leukocyte culture. In such conditions, both cell growth and viability can be checked easily by direct visualization of the culture flask under an inverted microscope.

Using conventional polystyrene flasks for large-scale expansion of blood-derived cells for clinical use (in this case, the cell numbers can rise up to 10^{11} with culture volumes in the range of liters) creates

obvious problems, both at the logistic level (i.e. laboratory space, number of laminar flow hoods, and incubators needed, etc.) and at the practical level (since the handling of these cultures may require a high number of specially trained personnel). Furthermore, because the cultured cells are to be reinjected into humans, important safety issues need to be considered such as insuring that the whole culture process is performed under sterile conditions (also referred to as good manufacturing procedures or GMP), minimizing contamination with microbial and other components (i.e. sera and/or antibiotics) whose presence may induce severe side-effects in humans.

These requirements have led in the last few years to the development of new culture technologies that have moved the traditional culture process from a human-based, rather artisanal level, to a sophisticated industrial level in which the 'human-work' component has been maximally limited. These new culture systems are presently used by various laboratories involved in cellular therapy studies. The aim of this entry is to give to the reader an overview on the latest technologies used for large-scale expansion of leukocytes for clinical use and their major medical applications. However, it is important to keep in mind that this field, boosted by the promising results obtained in different cellular therapy applications, is in continuous and fast development; new products with improved features are regularly appearing on the market with the ultimate goal of allowing the production of the largest possible number of clinical-grade blood-derived cells at the lowest possible price.

Culture media

Historically, mononuclear blood cells have always been cultured *in vitro* in a medium (usually RPMI 1640 or IMDM) containing serum as a source of undefined growth supporter. FBS and pooled human AB serum are routinely used in this system. However, cells intended for clinical use should preferably not be cultured with animal or human sera due to

possible viral transmissions and side-effects, including patients' anaphylactic reactions caused by the presence of xenogeneic/allogeneic proteins remaining on the cell surface. Therefore, when possible, serum-free culture media should be used for cells intended for patient reinfusion. In response to this need, different companies have developed serum-free media (Table 1) specifically designed to support the *in vitro* growth of T cells, such as LAK cells and TILs, or hematopoietic progenitors, such as CD34⁺ cells. In addition, the media used for *in vitro* expansion of blood-derived cells for reinjection into humans must be endotoxin-free (endotoxin units (EU) <0.05 per ml) and, if possible, antibiotic-free. When the addition of antibiotics is required, preference is to be given to antibiotics for which the risk of allergic reactions is low (such as gentamycin sulfate). Consequently, β -lactamic antibiotics (e.g. penicillin) will not be used.

Growth and/or differentiation factors (such as GM-CSF, G-CSF, IL-3, stem cell factor (SCF) for hematopoietic progenitors, IL-2 for LAK cells and TILs, IL-4, GM-CSF and tumor necrosis factor α (TNF α) for dendritic cells) are usually added to the culture media to support the growth and/or potentiate the biological functions of these blood-derived cells. Only commercially available and purified recombinant human growth factors can be used in clinical-grade cultures. Conditioned media containing 'growth factor activities' cannot be used to grow cells for use in humans.

Tissue culture vessels

As described above, traditionally, cultures of blood-derived cells have been performed in polystyrene flasks of different sizes (ranging from 25 to 225 cm²). Although flasks represent an excellent tissue culture vessel for most leukocytes growing either in suspension (such as lymphocytes) or adhering to plastic surfaces (such as macrophages and dendritic cells) and allow monitoring of cell growth by visual inspection under an inverted microscope, they can hold logistic

and practical problems when the number of cells to be cultured becomes very high (>10⁹ cells). These problems include incubator space (Figure 1), time and support personnel required for cell manipulations, and high risk of microbial contaminations. In this latter respect, cell culture bags represent an improvement over flasks by providing a closed system from the time the cells are initially collected from a patient/donor, cultured and then reinfused into the patient. Moreover, the bags are single-use vessels, thus preventing any possibility of patient sample cross-contamination, and can be easily disposed of after use. More importantly, they greatly facilitate the handling of large-scale cultures since a single technician can easily manage up to 50–100 l of tissue culture at a time.

The two companies producing commercial cell

Figure 1 Large-scale expansion of leukocytes in T-175 polystyrene flasks. A standard-size incubator can hold an average of 64 flasks containing a maximum of 150 ml of cell culture each (total capacity per incubator – 9.6 l of cell culture and about 10¹⁰ total cells).

Table 1 Serum-free media for leukocyte growth

Medium	Manufacturer	Applications
AIM-V	Gibco, Grand Island, NY	LAK cells and TILs
X-VIVO-10	BioWhittaker, Walkersville, MD	LAK cells and TILs
HB-LAK	DuPont, Wilmington, DE	LAK cells
HL-1	Ventrex, Portland, ME	LAK cells and TILs
X-VIVO-15	BioWhittaker, Walkersville, MD	Hematopoietic progenitors
Progenitor-34	Life Science Tech., Gaithersburg, MD	CD34 ⁺ progenitors

culture bags are Baxter Healthcare Corp. (Immunotherapy Division, Irvine, CA) and American Fluoroseal Corp. (Silver Spring, MD). Baxter cell culture bags are sold under the trade names of Lifecell and Cryocyte. American Fluoroseal provides the Teflon cell culture bags. They come in different sizes ranging from 50 to 3000 ml maximum bag capacity (with culture volume ranging from 100 to 1500 ml, respectively). Importantly, Lifecell culture bags can be used in conjunction with the Lifecell solution transfer pump (Figure 2), thus allowing a drastic

reduction in the risk of cell contamination, biohazard exposure, feeding time and occupied incubator space. Finally, culture harvesting is also facilitated by direct centrifugation of the cells in the bags using specially designed bag holders that fit into large centrifuge cups, such as the ones used in Sorvall centrifuges.

A number of factors need to be considered in the use of plastic cell culture bags:

1. The kinetics of cell growth varies with each cell type, creating specific requirements for culture medium components and/or oxygen and carbon dioxide.
2. Bag surface properties will affect growth. Adherent cells cannot adhere to gas-permeable plastic bags so they cannot be used to grow, for instance, dendritic cells.
3. Gas permeability is a critical factor. Oxygen limitation can occur in culture bags in which the material is not sufficiently gas permeable and the proper feeding schedule is not maintained. Currently, a limited number of bag materials are available that provide the appropriate necessary gas exchange for cell culture. However, depending upon the cell being cultured, an increase in cell proliferation can be achieved by simply altering the incubator gas conditions (10% carbon dioxide and 30% atmospheric oxygen have been shown to be the best gas conditions for LAK cells and TILs grown in Lifecell bags).
4. Appropriate volumes and cell surface ratio should be used. Using the optimal culture medium depth is important for gas diffusion and delivery of oxygen to the cells. In this respect, one should consider that the nominal bag size is usually much greater than the optimal culture volume. Bag cell cultures can be initiated at low volumes and fed during the culture period by simply adding more culture medium and recombinant growth factors to the bags.

Finally, a disadvantage of cell culture in gas-permeable culture bags is the impossibility of visually checking the growth and viability of the cells while they are inside the bag (Table 2). Periodic sampling of the cultures is therefore needed to monitor their growth.

Tissue culture bioreactors

Currently, two different kinds of bioreactors are available. These bioreactors have been proven by different investigators to grow cells effectively (including blood-derived cells) to clinically useful

(A)

(B)

Figure 2 Large-scale expansion of leukocytes in gas-permeable cell culture bags. Bags can be filled up manually (A) using a gravity transfer set (arrows) or using a solution transfer pump (B). An incubator can hold an average of 30 bags containing a maximum of 1500 ml of cell culture each (total capacity per incubator = 45 l of cell culture and about 2.5×10^{11} cells). b, gas-permeable cell culture bag; m, medium.

Table 2 Comparison of polystyrene flasks versus gas-permeable bags as tissue culture vessels for large-scale leukocyte expansion

	Flask	Bag
Surface area ^a	25–225 cm ²	60–750 cm ²
Culture volume	10–150 ml	20–1500 ml
Cell type	Adherent and suspension	Not indicated for cells that need anchorage
Visual inspection	Possible	Not possible
Risk of contamination	High	Low
Feeding time	Long	Short
Incubator space	Large	Small
Cell harvesting	Laborious/long	Easy/quick

^aSurface area refers only to one side of the vessel.

quantities while significantly reducing cost, time and space requirements. They include the 'hollow fiber cell culture bioreactors' (namely Cellmax 100, Celco Advanced Bioreactors, Kensington, MD) and the 'rotary cell culture system' (Synthecon Inc., Houston, TX). Both systems provide a three-dimensional growth environment that mimics the parental tissue structure and function (Table 3).

Hollow fiber cell culture bioreactors

These bioreactors allow *in vitro* cell growth within artificial capillary beds. As shown in Figure 3, they consist of a standard glass medium bottle serving as reservoir, a stainless steel gear pump, an autoclavable hollow fiber cartridge (in which cells are cultured) connected with two side-port glass bottles (used for cell inoculation and harvesting procedures), medical grade silicon rubber tubing serving as gas exchanger to maintain the appropriate culture medium pH and pO₂, a stainless steel tray of sufficiently small dimensions to enable two such systems to fit within a standard tissue culture incubator (Figure 3), and a pump motor magnetically coupled to the pump that can be lifted from the system when it needs to be removed from the incubators. The pump speed and flow direction are determined by an electronic control unit which sits outside the incubator and is connected to the pump motor via a flat ribbon cable which passes through the gasket of the incubator door.

Cells are inoculated into the extracapillary cartridge space and settled out of the capillary surface. Tissue culture medium, drawn from the reservoir, is pumped through the hollow fiber lumen; the cells are subsequently nourished within the artificial capillary network, in which nutrients and oxygen in the circulating medium readily diffuse through the capillary walls (available in different pore sizes). Metabolic waste products similarly diffuse away from the cells and are diluted in the circulating medium. Because of their high molecular weight, secreted growth factors, which are often cell-specific and feedback-regulated within the sphere of influence of each cell, are preserved within the extracapillary space, thereby maintaining a stable environment similar to the *in vivo* physiological conditions.

In many applications, the combination of physiological concentrations of nutrients, oxygen, growth factors and physical support, and low levels of metabolic waste enable the cells to fill the entire extracapillary space, forming nearly solid cell masses within the network of artificial capillaries. In artificial capillary cell culture systems (as in the bag culture system), the growing cells cannot be visualized within the cartridge capillary bundle. However, useful cellular growth data can be generated by monitoring the depletion of the medium carbon source and the increase in catabolic products (Figure 4). Such measurements are a direct window into the cell

Table 3 Characteristics of different leukocyte culture systems

Culture system	Shear stress	Mass transfer	Dimensionality	Colocation of dissimilar cell types	Cell density (cells ml ⁻¹)
Static (flasks/bags)	None	Adequate 2D	3–4 layers 2D	Limited	0.3–1 × 10 ⁶
Roller bottles	Moderate	Good 2D	3–4 layers 2D	Very limited	1–5 × 10 ⁶
Hollow fiber	None	Good	3D	Limited	10 ⁷ –10 ⁸
NASA bioreactor	Very low	Good	Excellent 3D	Good	10 ⁷ –10 ⁸

2D, two-dimensional; 3D, three-dimensional.

Each bioreactor can maintain up to 10^{11} cells. 1, medium bottle; 2, hollow fiber cartridge; 3, side-port connections to glass bottles for cell inoculation and harvesting; 4, pump; 5, pump motor magnetically coupled to the pump; 6, flat ribbon cable connecting the pump to an electronic control unit (7) which sits outside the incubator and determines pump speed and flow direction; 8, stainless steel tray.

physiology: in fact, glucose consumption and concomitant lactate production are both directly related to cell growth.

Daily maintenance of an extremely high cell number growing in a cartridge is reduced to: 1) daily monitoring of the lactate/glucose concentrations in the reservoir bottle, and 2) cell feeding by simply changing the medium bottle when the medium has become depleted. This refeeding procedure requires approximately 5 min. The extrafiber space is drained periodically to either harvest the culture medium, presumably enriched in nondiffusible products secreted by the cells, or to evaluate the cell number and functional characteristics. This is accomplished in a laminar flow hood by draining the extrafiber fluid by gravity into one of the two side-port bottles. This procedure requires 20–30 min. A single Cellmax 100 cartridge can maintain up to 10^{11} cells, equivalent to 400–1000 T-175 polystyrene flasks. In fact, Cellmax 100 bioreactors have been successfully used by different laboratories for expansion of LAK cells,

Figure 4 Typical glucose consumption (g day^{-1}) curve of a hypothetical leukocyte culture in hollow fiber cell culture bioreactor showing logarithmic increases over time.

TILs and, more recently, CD34⁺ cells for clinical use (see below).

Rotary cell culture system

These bioreactors are based on principles derived from microgravity research (Figure 5). Most culture systems address one specific parameter, e.g. shear force, at the expense of others, such as mass transfer of nutrients and metabolic wastes, three-dimensionality, and/or cocultivation of dissimilar cell types. The rotary cell culture systems are the first bioreactors designed to simultaneously integrate cocultivation, low shear, high mass transfer, and three-dimensional growth without sacrificing other parameters (Table 3). The microgravity-based bioreactor was developed at the NASA-Johnson Space Center (Houston, TX) and is a zero-head space, aqueous medium-filled bioreactor suspending particles by rotating the vessel wall and integral gas diffusion membrane around the horizontal axis. This rotation can hold particles up to 1 cm diameter in orbital suspension, as the sedimentation forces induced by gravity are balanced by the centrifugal force generated by the vessel rotation. Nonadherent cells may be cultured in suspension while adherent cells are grown on microcarriers. In its simplest form,

(A)

(B)

the system has a capacity of 125–500 ml (Figure 5A) and can support the cultivation on microcarriers of masses up to 1 cm diameter and cell concentrations of at least 10^7 cells ml^{-1} . The rotary cell culture system has a wide range of cellular and clinical research applications, including cancer research, *in vitro* toxicology testing and tissue engineering.

The cell types grown in the rotary cell culture system are listed in Table 4. Although lymphocytes to be used in adoptive immunotherapy have been reported by several laboratories to grow successfully in these bioreactors, the major advantage of this cell culture system over the ones described above is the possibility of growing differentiated three-dimensional tissues, thus resembling the parental tissue structure and function more closely than any other *in vitro* culture system currently available.

Table 4 Cell types grown successfully in the rotary cell culture system

<i>Suspension cultures</i>	<i>Adherent cultures</i>
Human lymphocytes	Human keratinocytes
Human hepatocytes	Human breast cancer
Mouse BM stem cells	Human prostate cancer
Human leukemic cells	Human lung cancer
	Human melanoma
	Human skin fibroblasts
	Human melanocytes

Clinical applications

Generation of LAK cells and TILs for use in adoptive immunotherapy

Adoptive cellular immunotherapy offers an alternative therapy for cancer patients who become unresponsive to conventional treatment protocols. The identification and expansion of lymphoid subpopulations able to mediate tumor regression upon adoptive transfer in the tumor-bearing host is an important tumor immunology goal. In the past 10 years, a great deal of attention has been focused on LAK cells generated by expansion of patients' lymphocytes (collected by multiple leukopheresis) in recombinant human (rh) IL-2 for 3–5 days. *In vitro*, these killer cells are capable of lysing a variety of autologous and allogeneic fresh tumor targets in an MHC nonrestricted fashion while sparing cells from normal tissues. Upon adoptive transfer in conjunction with systemically administered rhIL-2, LAK cells were proven effective in clinical trials by reducing metastatic tumor burden in cancer patients. A major problem in these therapies has been the *in vitro* activation of large number of peripheral blood lymphocytes (up to 2×10^{11} cells) obtained from successive leukopheresis. LAK cells for clinical trials have been successfully cultured in polystyrene flasks and roller bottles and, more recently, in large size (up to 3000 ml) gas-permeable culture bags using serum-free media formulations (AIM V and X-VIVO) and high doses (up to 1000 U ml^{-1}) rhIL-2.

TILs are lymphoid cells infiltrating solid tumors, which can be grown *in vitro* with rhIL-2. Theoretically, TILs have been primed against the autologous tumor by prolonged *in vivo* exposure and have a 50–100-fold increased ability to induce tumor regression, as compared to LAK cells. Their lack of efficacy in eliminating the tumor *in situ* is probably due to their insufficient numbers, and/or local tumor-mediated immunosuppression. However, TIL preparation, even using new technologies, is still cumbersome: classically, tumors are enzymatically digested

into single tumor cells and an average of 15% lymphocyte suspensions. The mixture is then cultured in polystyrene flasks with AIM-V or X-VIVO 10 media in the presence of high doses of IL-2 (1000 U ml^{-1}) leading to selective outgrowth of TILs with concomitant tumor cell demise. When the cell cultures reach about 0.5 l, they are usually transferred to culture bags (LifeCell or Teflon) which are incubated in a flat position on perforated shelves without agitation for 3–5 days in 37°C humidified 10% CO_2 /air incubators. Recently, in some laboratories, TIL suspensions harvested from culture bags at a 5×10^8 – 10^9 cell concentration are further expanded to high cell numbers (up to 2×10^{11} cells) required for human clinical injections using hollow fiber bioreactors. The rates of TIL growth in the gas permeable bags currently used and in the Cellmax 100 bioreactors are similar. Likewise, phenotypic and cytotoxic characteristics of TILs obtained from either culture method are not significantly different. However, the use of Cellmax 100 bioreactors is accompanied by an 80% reduction in the technician time and incubator space required, as compared to bag cultures.

Culture of CD34⁺ cells and *in vitro* generation of hematopoietic precursors for bone marrow reconstitution

Bone marrow transplantation (BMT) is increasingly used for the treatment of many malignant and non-malignant disorders. The use of autologous bone marrow cells has the advantage of avoiding the immunological complications of allogeneic BMT, but has the disadvantage of requiring the use of bone marrow, which potentially contains neoplastic cells from patients who have also undergone extensive chemotherapy. These complications may lead, on the one hand, to slow and incomplete marrow recovery and, on the other hand, to higher risk of relapse. Recently, cell-processing systems have been developed for the purification of bone marrow and peripheral blood-derived stem cells used for hematopoietic reconstitution following high-dose chemotherapy treatment protocols. Several clinical studies comparing traditional BMT and CD34⁺ stem cell reconstitution showed for the latter treatment reduced infusional side-effects while maintaining equivalent time for neutrophil engraftment. In this respect, however, following high-dose chemotherapy protocols, a severe neutropenia always develops in spite of reconstitution using autologous stem cell transplantation.

This neutropenia is the leading cause of morbidity and mortality from infections, requiring inpatient supportive care and contributing to the high therapy cost. The use of hematopoietic growth factors has

reduced but not eliminated this period of leukopenia. Studies have demonstrated that the use of peripheral blood stem cells mobilized by chemotherapy and/or growth factors gives rise to faster hematologic recovery than BMT. However, the duration of the severe neutropenia after these transplants is always at least 7 days, irrespective of the method of mobilization or the number of hematopoietic progenitor cells infused. This 7 day interval is now seen as the minimum necessary time for transition from mobilized stem cells to band/mature granulocytes. A solution to further decrease or eliminate this neutropenia is to generate *in vitro* cells capable of resolving the neutropenia.

Several investigators have examined *in vitro* expansion and maturation of hematopoietic precursors in liquid cultures originating from enriched CD34⁺ cell preparations stimulated with IL-3 and/or GM-CSF or G-CSF, or SCF either in gas-permeable plastic bags or in hollow fiber bioreactors. These studies have shown that enriched CD34⁺ precursors can proliferate and differentiate *in vitro*. However, there is not yet certainty that the duration of neutropenia can indeed be shortened by infusion of progenitor cells cultured *in vitro* in any of the listed conditions.

Culture of dendritic cells for use in active immunization

Dendritic cells (DCs) are potent antigen-presenting cells specifically involved in the initiation of antigen-specific immune responses. Because of their potent costimulatory activity, they are well suited to prime naive T cells toward various antigens such as viral peptides or alloantigens. The bone marrow origin of DCs has been shown in transplantation studies and recently described using cord blood and CD34⁺ peripheral blood progenitors *in vitro* in conjunction with a cytokine cocktail (SCF, EPO, IL-1 β , IL-3, IL-6, and GM-CSF) with either TNF α or IL-4. The recent possibility of growing relatively large numbers of these cells in culture (1×10^6 precursor cells can be expanded up to 5×10^7 mature DCs) provides a potent source of antigen-presenting cells from individual patients for vaccination protocols against infectious or tumor-associated antigens.

LEWIS^x/SIALYL-LEWIS^x (CD15/CD15S)

Ten Feizi, The Glycosciences Laboratory, Imperial College School of Medicine, Northwick Park Hospital, Harrow, UK

With the advent of the hybridoma technology, researchers from many areas of biology and medicine embarked on programs of monoclonal antibody production in order to identify functionally important antigens that appear at specific stages of embryonic development, cellular differentiation, and in oncogenesis. It is remarkable that the blood group-related antigen, Lewis^x (Le^x, **Figure 1**), featured in all three of these contexts. Moreover, following these assignments, a fascinating story has unfolded with assignments of important roles to Le^x and related oligosaccharide sequences on glycoproteins and glycolipids as ligands for the selectins. These are the leukocyte-endothelium adhesion molecules which have crucial roles at the initial stages of leukocyte recruitment in inflammation.

Murine stage-specific embryonic antigen 1 (SSEA-1) is Le^x

In the search for embryonic antigens with biological roles, antibodies were raised to the murine teratocarcinoma line, F9, as a representative of relatively undifferentiated embryonic cells. A stage-specific embryonic antigen, SSEA-1, was detected by hybridoma antibody anti-SSEA-1. On the embryo, the antigen appears at the 8-cell stage coincident with the onset of compaction (the tight adhesion of the embryonic cells to one another). In the course of embryonic cell differentiation and development, expression of the antigen diminishes, and in the adult mouse its expression is restricted to limited areas of the nervous, reproductive and genitourinary systems. SSEA-1 was identified as the trisaccharide sequence consisting of fucose joined by α 1–3 linkage to the N-acetylglucosamine of a type 2 blood group backbone (galactose β 1–4 linked to N-acetylglucosamine), and borne on high molecular weight glycoproteins. This

Figure 1 The inter-relationships between the carbohydrate antigens Le^x, Le^y, sialyl- and sulfo-Le^x (based on the type 2 backbone sequence Galβ1–4GlcNAc), their isomers Le^a, Le^b, sialyl- and sulfo-Le^a (based on type 1 backbone Galβ1–3GlcNAc), the i, I and Fc10.2 antigens, and the major blood group antigens H, A and B. The i and I antigenic determinants are expressed on nonsubstituted or accessible, repeating, type 2 backbone sequences, and Fc10.2 on a type 1 disaccharide backbone joined to a type 2 backbone. The 'hybrid' backbone structure with a type 2 and a type 1 branch expresses one of the I antigenic determinants, I(Ma), which consists of the Galβ1–4GlcNAcβ1–6Gal sequence. The major blood group antigens are expressed on either type 1 or type 2 backbones and on additional backbone families (not shown here). Fuc, fucose; Gal, galactose; GlcNAc, *N*-acetylglucosamine; NeuAc, *N*-acetylneuraminic acid; HSO₃, sulfate.

structure termed Le^x, is an isomer of blood group Lewis^a (Le^a) which consists of type 1 backbone (galactose β1–3 linked to *N*-acetylglucosamine) which is α1–4 fucosylated at *N*-acetylglucosamine. Further fucosylation of Le^x and Le^a with fucose α1–2 linked to the terminal galactose constitute the Le^y and blood group Le^b antigens, respectively. The inter-relationships of Le^{x/y}, Le^{a/b} with the major blood group antigens H, A and B are shown in Figure 1.

The backbone sequences are antigens in their own right when they are not further glycosylated and are accessible. Thus, the repeated type 2 backbones in linear sequence express the i antigen, and when branched, the large I antigen (Figure 1). Rather ahead of the applications of hybridoma antibodies, the human monoclonal autoantibodies, anti-i and

anti-I, were used as sequence-specific reagents, and some striking changes were noted in the expression of these antigens during early murine embryogenesis, I being the predominant antigen in the early embryo, and i appearing coincident with the first differentiation event in the embryo, i.e. the formation of the primitive endoderm. From the observations with the monoclonal antibodies, together with earlier knowledge that marked changes occur in the expression of the major blood group antigens in human fetal organs at various developmental stages, a picture emerged that some of the changes in antigenicities of glycoproteins and glycolipids of cells during successive developmental stages may be brought about by sequential addition or deletion of monosaccharide residues. This led to the proposal that Le^x, I and i and other oligosaccharides of the blood group family

may have important biological roles as recognition structures. They seemed excellent candidates as 'area codes' which determine cell migration pathways, for example.

A functional antigen in early neural development, L5, is Le^x

L5 antibody, originally raised to glycoproteins of the murine nervous system, was shown to recognize neurons and astrocytes in the cerebellum. Later observations on the chick embryo have suggested that the L5 antigen plays a role during early neural development. The antigen has been detected on multiple brain glycoproteins including Thy-1, and on a chondroitin sulfate proteoglycan. The structure of this antigen has been elucidated recently by generating oligosaccharide probes (neoglycolipids) from N-glycans released from total antigen-positive glycoproteins, and from Thy-1 isolated from the brain. The L5 antigen was shown to consist of Le^x. The various attributes for L5 antigen in the development of the nervous system can therefore be assigned to the Le^x sequence. By other approaches, it has been shown that astrocytes in the developing brain and astrocyte subpopulations in adult cerebellum express the Le^x antigen, and there is increased expression on the cell processes at sites of injury. It has been suggested that Le^x and related sequences may be ligands for carbohydrate-binding proteins that mediate astrocyte–neuron and astrocyte–matrix interactions.

Le^x and sialyl-Le^x are markers of human granulocytes and monocytes, and have been designated CD15 and CD15s, respectively

The production of antibodies to distinguish different human blood cell types and lineages has been a major application of the hybridoma technology. Innumerable antibodies that clearly distinguish granulocytes from other blood cells were among the earliest to emerge. The antigenic determinants of one of these antibodies, VEP8, and the second, VEP9, which, in addition binds monocytes, were shown to be Le^x. These findings highlighted a difference between the human and mouse cellular markers, for, in the adult mouse Le^x is not readily detectable immunochemically on blood cells of any kind. Innumerable antibodies with similar specificities toward human granulocytes have been produced over the years, and are assigned as CD15. Desialylation of human blood cells revealed a strong reactivity of human monocytes with anti-Le^x as well as granulocytes, indicating that monocytes express pre-

dominantly the sialyl-Le^x, and that the sialic acid results in masking of the expression of Le^x antigen. Antibodies that recognize the sialyl form of Le^x (Figure 1) on cells of the myeloid series are now designated CD15s.

Le^x and sialyl-Le^x are tumor-associated antigens

Another intensive area of research that became stimulated by the advent of the hybridoma technology was the search for tumor-associated antigens that might be targets for immunotherapy. Among promising antibodies isolated, by comparing reactivities with tumor cells and their normal counterparts, were those which upon further investigation were found to be directed at carbohydrate sequences of glycoproteins and glycolipids. Disappointingly for those who were hoping to identify targets for a new generation of therapeutic monoclonal antibodies ('magic bullets'), the carbohydrates identified were not unique to the tumors, but were sequences that occur normally on other cells and tissues of the body. Notable examples were antibodies directed to Le^x and sialyl-Le^x. Thus, these oligosaccharides may have been inappropriately expressed on the cancerous cells being investigated, but, as discussed above, they were already established as 'distinctive markers' of myeloid cells among human peripheral blood cells. The conclusions of the present author were that either these findings were a reflection of limitations of the methods of selection of hybridoma antibodies, or they were pointers to roles for the carbohydrate structures not only as area codes but also as ligands for growth and differentiation.

Le^x and Le^a-related sequences as ligands for carbohydrate binding receptors, the selectins

The concept that oligosaccharides can serve as area codes has been corroborated by developments in leukocyte biology and inflammation research, notably from work with the leukocyte–endothelial adhesion molecules, the three selectins. The molecular cloning of these molecules, E- and P- selectins (CD62E, CD62P) of endothelia and L-selectin (CD62L) of leukocytes, and the finding that each contains a lectin-like domain, stimulated intensive research into their oligosaccharide ligands. Knowledge that the E- and P-selectins bind to granulocytes and monocytes focused research on Le^x and sialyl-Le^x as obvious candidate ligands. Indeed, all three selectins can bind to sialyl-Le^x-related sequences when these are displayed in the clustered state on protein or lipid (E-

selectin can also bind the asialo-Le^x sequence, although less avidly). The isomeric sialyl-Le^a-related sequences (found at the surface of epithelial tumors) are rather more strongly bound than the Le^x analogs. In addition, the sulfated Le^a and Le^x sequences (identified on an ovarian cyst adenoma glycoprotein) are also bound avidly. On endothelial venules (sites at which L-selectin-mediated leukocyte adhesion occurs), variously sulfated forms of the Le^x sequence have been identified. Details of the macromolecular carriers of these oligosaccharide ligands are out of the scope of this entry: suffice it to say that oligosaccharides of this family are key players in the selectin recognition systems. Unlike the usual situation of receptor–ligand pairs, however, a picture is emerging of recognition systems that operate as triads: receptors, ligands and carriers. Here the receptors are lectins (the selectins), the ligands are oligosaccharides, but only when they are optimally expressed and presented on carriers (proteins or lipids) are functional counter-receptors formed. Also a possible involvement of these carbohydrate structures in the process of metastases has been suggested, the proposed mechanism being that sialyl-Le^x- or sialyl-Le^a-positive cancer cells hijack the leukocyte adhesion pathway for extravasation.

LIFESPAN OF IMMUNE CELLS AND MOLECULES

David Gray, Department of Immunology, Royal Postgraduate Medical School, Hammersmith Hospital, London, UK

A complete understanding of the immune system relies not only on knowing the detailed functions and interactions of its cells and molecules, but also on knowledge of the population kinetics of those cells. Our theories of how immune responses are initiated and regulated, and, for instance, how both tolerance and memory are induced and maintained, are based on assumptions about the production of lymphocytes from primary lymphoid organs (bone marrow and thymus) and on the turnover of these lymphocytes in the periphery.

Measurement of lymphocyte lifespan

Most methods of measuring lifespan rely on identifying cells that have gone through cell cycle and, therefore, the usual definition of lifespan is the period elapsing between cell divisions (intermitotic lifespan). This is usually assessed by labeling cells in cycle with identifiable DNA precursors such as tritiated thymidine (³H]TdR) or bromodeoxyuridine (BrdU). Obviously, some cells (e.g. plasma cells) may not divide once derived from a precursor population and leave the system through cell death. However, all cells of the immune system are derived from cycling precursors in primary lymphoid organs, and so the rate of accumulation of labeled cells during continu-

ous infusion of [^3H]TdR can be used as a measure of the 'average lifespan' within a population. This method has its drawbacks: if too much label is used it can have direct toxic effects on lymphocytes, or indirectly cause polyclonal activation due to breakdown of the intestinal wall. If too little label is used, rapid decay of the DNA precursors *in vivo* leads to an underestimate of cycling cells. Other methods are available, such as the selective killing of cycling cells by cytotoxic drugs (e.g. hydroxyurea). Persistence of marked cells after adoptive transfer only gives an estimate of the clonal lifespan, as it does not take into account cell division subsequent to transfer.

Population kinetics of B lymphocytes

Production of B cells in the bone marrow proceeds at an enormous rate. In both mice and rats the bone marrow produces enough B cells to repopulate the peripheral lymphoid organs within 3–5 days (5×10^7 per day in mice, 3×10^8 per day in rats). Most, if not all, of these cells are exported from the marrow into the bloodstream. At face value then, the peripheral B lymphocyte pool (i.e. in spleen, lymph nodes, Peyer's patches etc.) should turn over completely within a few days (Figure 1). However, this assumes that all of the newly produced B lymphocytes have free access into the secondary lymphoid organs. Certainly, there is no barrier for entry into the spleen from the blood supply; however, in lymph nodes, cells must cross high endothelial venules, a process mediated by specific surface molecules that are not

expressed uniformly by all lymphocyte subsets. Several studies have shown that B cells newly emerged from the marrow do not immediately enter the areas in which most recirculating B cells localize, i.e. in lymphoid follicles. Stable incorporation of new B cells into the peripheral pool is estimated at 5–10% of the output of the bone marrow. Therefore, at least 90% of new B cells exit the system very quickly, their lifespan being only 3–4 days. Most of this time is spent in the spleen, probably in the red pulp; entry into the white pulp, and hence to follicles, is restricted.

Encounter with antigen is one of the factors that can mediate entry of new cells into this stable, recirculating pool; following immunization there is a wave of activation and incorporation of newly produced, antigen-specific B cells into the peripheral pool. Interestingly, if antigen is localized only in lymphoid follicles or in lymph nodes, no such wave of incorporation occurs, illustrating the restricted migration path of newly produced B cells. Selection for entry into this pool is not mediated solely by exogenous antigen: comparison of the V gene repertoire of IgM $^+$ IgD $^+$ B cells in the bone marrow (newly produced) and in the spleen (stable, recirculating) reveals a bias in the latter population that suggests a ligand selection process has taken place; however, the biased repertoire of the splenic population is similar in germ-free mice. Competition for niches within the follicular microenvironment seems to work at the level of signaling via immunoglobulin, as self-reactive transgenic (i.e. monoclonal) B cells when

Figure 1 B lymphocyte population dynamics.

exposed to antigen are excluded from follicular entry when in competition with the polyclonal repertoire of normal B cells. Antigen-independent mechanisms of selection may also occur.

The 5–10% of new B cells that become incorporated now begin to recirculate, by which we mean that they move from the spleen into the bloodstream, then cross high endothelial venules to enter lymph nodes or Peyer's patches, migrate to follicles and, after a time, leave via efferent lymphatics, eventually to return to the blood. B Lymphocytes within this recirculating pool have an intermitotic lifespan of several weeks. Determinations of B cell lifespan have varied widely, depending on the method of assessment. In general, the use of cytostatic drugs has led to shorter estimates than those obtained by labeling dividing cells. Controlled use of BrdU in nontoxic doses indicates that the average lifespan of a recirculating B cell is around 4 weeks in mice. These experiments cannot rule out the existence of B cells with much longer lifespans.

Encounter with antigen activates B cells and stimulates cell division. The number of B cells entering this activated pool comprises less than 1% of the peripheral pool per day. Activation of B cells in follicles (by antigen on follicular dendritic cells) leads, in the second week of the immune response, to the formation of germinal centers. B cells proliferate very rapidly within germinal centers with an estimated cell cycle time of only 7–8 h. These structures are important in the clonal expansion of memory cells and generate high-affinity somatic mutants. The strong selection against nonantigen-binding mutants means that only 10% of germinal center B cells ever leave to rejoin the recirculating pool. The rest die by apoptosis and are rapidly engulfed by tingible body macrophages.

The B cells that have undergone antigen-driven proliferation and returned to a resting state are classically thought of as memory cells. While traditionally, memory B cells have been regarded as very long-lived, recent experiments have shown that external factors, such as antigen stimulation, may play a role in their maintenance. The persistence of memory B cells over long periods may not be a reflection of their longevity, but rather the intermittent stimulation they receive from long-term depots of antigen (as immune complexes on follicular dendritic cells). In the absence of antigen, memory B cells seem to have a lifespan that is similar to B cells of the peripheral pool in general; unfortunately there is no consensus on its exact length, estimates varying from 1 to 6 months.

Following antigenic stimulation, a large proportion of B cells differentiate into high-rate anti-

body-producing cells, i.e. plasma cells. The majority of plasma cells survive in this terminal state for only 3–4 days. However, in certain sites, subpopulations of plasma cells can live much longer. In the mouse lamina propria of the gut 50%, and in the bone marrow 90%, of plasma cells secreting immunoglobulin G (IgG) and IgA have lifespans in excess of 3 weeks. All IgM plasma cells are short-lived. The bone marrow is the major source of serum antibody and the production of antibody following immunization can be extremely long (>25 years). This is likely to be due to continual antigenic stimulation and replenishment of the plasma cell pool. However, a very long-lived population of antibody-secreting cells has not been ruled out.

In this section we have considered only the B2-type B cells that make up the vast majority of the recirculating pool. The B1 cells (CD5, Ly1 B cells) may form a separate lineage that predominates in the peritoneum and responds only to T cell-independent antigens. As these cells are not produced in the adult bone marrow beyond 3 weeks of age, they seem to be self-renewing. Their intermitotic lifespan has not been closely studied, but appears to be in the order of a few weeks.

Population kinetics of T lymphocytes

The adult thymus, unlike the bone marrow, exports too few cells to account for the turnover of T cells in the periphery. Between 1 and 2×10^6 T cells leave the thymus each day. By careful use of BrdU the average lifespan of T cells in the peripheral pool is estimated at 4–6 weeks. This means that around 5% of the pool turns over daily; input from the thymus accounts for 0.5–1% (assuming the T cell pool in mice is 2×10^8). Adult thymectomy of mice allows assessment of the turnover of peripheral T cells in the absence of thymic-derived input; when this is done the average lifespan increases to 3–4 months. An average lifespan figure does not take into account the fact that some populations of T cells turn over more rapidly than others. In recent years careful studies have dissected the dynamics of different populations of T cells. Naive T cells (CD45 RA⁺, CD44^{lo}) may have a lifespan of 6 months or more. In contrast, T cells with an activated or memory phenotype (CD45 RA^{lo}/CD45 RO⁺, CD44^{hi}) turn over much more rapidly, with a lifespan of 3–4 weeks (Figure 2). Again these 'memory' T cells are a mixed bag, consisting of bona fide memory cells, as well as recently activated cells and effector cells. At present it is difficult to distinguish these cells. Certainly it is clear that even after long-term infusion of mice with BrdU, 20% or more of memory cells

Figure 2 T lymphocyte lifespans.

remain unlabeled, indicating that some of these cells may be long-lived and evidence suggests that some memory T cells revert to a naive phenotype. CD8⁺ T cells appear to have a slightly longer lifespan than CD4⁺ T cells. Based upon the small amount of data available, $\gamma\delta$ T cells differ little in lifespan from $\alpha\beta$ T cells.

Like B cells, the persistence of memory T cells is influenced by continued antigenic stimulation, however, its obligatory role is still controversial. Recent evidence suggests that CD8⁺ T cells may be less antigen-dependent than CD4⁺ T cells. The study of this question and others relating to lymphocyte lifespan may be facilitated by the use of TCR transgenic mice, as it will then be possible to follow the fate of a cohort of antigen-specific cells in the presence or absence of antigen. However, there are pitfalls to avoid with this methodology. Transfer into empty vessels, such as SCID (severe combined immunodeficiency) or RAG1/RAG2-deficient mice may give rise to exaggerated estimates of lifespan as there is no pressure upon the reconstituting cells from repopulating precursors from primary lymphoid organs. Conversely, transfer into intact mice may give very short estimates, although potentially a stable chimerism can be achieved that would allow analysis of the subsequent decay in numbers over time. For reasons not entirely clear, but probably due to encounter with environmental or cross-reactive antigens, T cells expand dramatically after transfer into depleted hosts. For this reason it may be necessary to use TCR transgenic mice that have been backcrossed on to a RAG-deficient background to circumvent antigen non-specific effects on cells with endogenous TCR rearrangements.

Effector T cells are generally thought of as terminally differentiated cells with a short lifespan (3–4 days). However, one theory of memory T cell development proposes that a small proportion of effector cells avoid cell death and become memory cells. It remains to be seen if this is correct or if memory and effector T cells develop along separate pathways of differentiation.

Lifespan of lymphocytes in humans

All of the figures discussed so far in this entry refer to the rodent immune system. There is some evidence that both T and B lymphocytes may live much longer in humans. Studies in patients who have either accidentally, or in the course of treatment, received a heavy radiation dose resulting in characteristic chromosome breakages that preclude mitosis, indicate that lymphocytes can persist for upwards of 10 years without dividing, although the damage to the DNA may itself have caused such longevity. Recently this type of study has been updated with the benefit of markers to identify T cell subsets: The data show that naive T cells (CD45 RA⁺) may have lifespans measured in years but that memory/activated T cells (CD45 RO⁺) turn over within months. As in mice, the reversion of memory cells to a naive phenotype has not been ruled out.

Molecules that regulate lymphocyte lifespan

It is currently thought that lymphocytes, like many other cells in the body, require signals from their environment to prevent the activation of a cell death program (apoptosis). Molecules of the bcl-2 family control the balance between death and survival. bcl-2, bclxL and other members of this family prevent the initiation of the death program that is set in train by molecules such as bax. Most mature, peripheral, recirculating lymphocytes express high levels of bcl-2. Occasionally lymphocytes undergo selection, for instance B cells in germinal centers, and during this process the levels of bcl-2 are dramatically reduced. Rescue from apoptosis is associated with a re-expression of the bcl-2 protein. Evidence from knockout mice suggests that bcl-2 may be less important for the selection that occurs during development of lymphocytes in the bone marrow or thymus, but that it is crucial for their long-term survival in the periphery. In bcl-2 knockout mice the mature, peripheral lymphocyte numbers fall dramatically within a few weeks of birth.

Turnover of accessory cells

The dendritic cells found in T cell areas of secondary lymphoid tissues are termed interdigitating cells. These cells are continually renewed by the influx into lymph nodes of veiled cells via the afferent lymph. [³H]TdR labeling suggests they are replaced from dividing precursors (in the bone marrow) at a rate of about 10% per day. This means that the average lifespan is around 5 days and the whole pool is exchanged within 3 weeks.

Dendritic cells found in B cell follicles are termed follicular dendritic cells (FDC). These cells appear to be extremely long-lived as befits their role in long-term antigen retention. No thymidine uptake has been noted in these cells following long-term infusion. Bone marrow chimeras made between H-2 disparate mice show no replacement of the host FDC population with donor FDC one year after construction, suggesting that FDC are not bone marrow derived and are not of the myeloid lineage (as interdigitating cells are).

The precursors of macrophages, monocytes, are produced in large numbers from the bone marrow. The transit time of these cells in the circulation is between 1 and 2 days, after which time they extravasate. Tissue macrophages do not seem to divide except at sites of inflammation and can persist for long periods (50–70 days). However, there are many different populations of tissue macrophages which may have differing lifespans. For instance, splenic red pulp macrophages turnover completely in bone marrow chimeras within one month, whereas macrophages in the adjacent marginal zone are replaced much more slowly (25% in one month).

Lifespan of immune molecules

Early measurements of the half-life of serum immunoglobulins relied on injecting purified protein labeled with radioactive iodine. This technique produced an estimated half-life of 4 days for 7S molecules. More recently, it has been possible to study half-life without labeling (potentially altering fine structure) by the use of monoclonal antibodies of defined specificity and/or heavy chain allotype. The results of such studies show that in mice IgM has a half-life of 2 days, for IgG3 and IgG1 it is 6–8 days, and for IgG2b it is 4–6 days; IgE has a half-life of 12 h and polymeric IgA 17–22 h. In humans, the use of antibodies in therapy indicates that the half-lives do not differ significantly from these figures.

Other immune molecules have much shorter *in*

vivo half-lives; cytokines decay within minutes, although exhaustive studies on the growing list have not been carried out. Complement components also are not well-studied in this respect but decay with a half-life of several hours, e.g. the half-life of C3 is 50 h.

LIMITING DILUTION ANALYSIS

Herman Waldmann, Immunology Division, Sir William Dunn School of Pathology, Oxford, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Why do we need it?

Progress in understanding how the immune system functions has relied a great deal upon 'readout systems' that require the introduction of antigen at one point in time, and quantitation of 'total response' (e.g. antibody levels) some time later. A large antibody response could have come from a few starting lymphocytes each responsible for high-level production, or it could have come from many lymphocytes producing far less. To fully understand the biology of the cellular events that follow antigen stimulation, one would like to know how many parent (or precursor) lymphocytes in a given starting population were triggered to produce the clones that eventually made the antibody. In other words, one would like to know the frequency of the precursor cells that exist within the starting population of lymphocytes, and the proportion of them that may be used in any response.

There is no simple (e.g. visual) way of being able to identify which of the cells in a large population will go on to produce an active clone. Antigen-specific precursors are rare and morphologically indistinguishable from the silent majority of resting lymphocytes. Limiting dilution analysis (LDA) allows the calculation of precursor frequencies as a retrospective process based on the measurement of the number of active clones generated from a given population of cells. As each active clone is derived from one precursor, then retrospectively one can estimate the frequency of precursor cells that gave rise to those clones.

Estimation of the precursor frequency can indeed be an end in itself, e.g. if one wished to determine the frequency of alloreactive cells that the bone marrow of a potential donor might have toward the graft recipient. Too high a frequency might reasonably predict aggressive graft-versus-host disease and would therefore be unacceptable.

The realization that there was a need for this sort of measurement in immunology, as well as the development of suitable technology to make it possible, led to the first important paper on the subject by Lefkovits in 1972, from which LDA has developed as an extremely powerful tool in immunology.

How is the frequency estimated?

The best way to understand LDA is to consider a specific example (Figure 1). Let us imagine that we have a population of lymphocytes from the blood of a potential bone marrow donor. We want to know the frequency of the precursors of cytotoxic T cells (pCTLs) that may react to the recipient. A simple *in vitro* approach would be to dispense these lymphocytes into many aliquots in microculture trays, each microculture tray getting a different input number. If one adds the best medium and all essential growth factors together with the recipient's irradiated stimulator cells, then any precursor lymphocytes should be activated to grow, and produce clones. Within the clones, the majority of daughter cells eventually differentiate into cytotoxic T cells lethal to the recipient's target cells. A simple chromium release assay can indicate which wells have made cytotoxic T cells and which have not. If the culture conditions have been good enough, then single precursors should have produced sufficient clone progeny to guarantee that all wells containing CTLs would be measurable in the readout.

Limiting dilution analysis relies upon the estimation of negative wells, as clearly these must have had no precursors. A positive well could have had one or more precursors and so is not so useful in the statistical analysis.

The proportion of cultures that fails to respond (i.e. has no pCTL within the lymphocyte aliquot) at any given lymphocyte input can be defined by the expression:

$$F_0 = e^{-u} \quad (1)$$

where F_0 is the number of negative cultures per total number of cultures, e the base of the natural logarithm, and u the average number of precursors (pCTLs) per culture (well). The above expression is the zero term of the Poisson distribution. The full Poisson distribution formula and its derivation is considered in detail in *Limiting Dilution Analysis of the Immune System* by Lefkovits and Waldmann.

If one modifies the above formula, one can derive the following expression:

$$u = -\ln F_0 \quad (2)$$

(this represents the conversion of formula (1) to its logarithmic form). Through this conversion, the for-

Figure 1 A single-hit curve. Four trays, each of 60 cultures, were inoculated with graded numbers of human lymphocytes (1250, 2750, 6250, 8750 cells per culture). Some of the cells in the inoculum are antigen specific, while the majority are irrelevant third-party cells. The dots in the upper row of trays indicate just the distribution of the antigen-specific cells. Culture conditions were chosen that allowed the cells of interest (dots) to have an optimum chance of proliferating and generating clones of cytotoxic T cells (CTLs). If the original parental T cells are called 'precursor' CTLs or pCTLs, then in the lower row of trays the dots represent the clones arising from the pCTLs. The CTL activity of each well is measured in a chromium release assay on the desired target cells. The cultures which scored positive are shown as 'filled' wells. In the first tray of 60 cultures, 24 responded. Therefore, F_0 is $36/60 = 0.6$. In the next three sets, we see that as cell input per culture well increases, the number and the proportion of negative cultures F_0 decreases. The results are plotted on a semilog plot and they fit a straight line. The vertical bars represent the 95% confidence limits. These represent the limits within which F_0 would be expected to fall 19/20 times. (Reproduced with permission from Lefkovits and Waldmann (1984).)

mula is reorganized around the value that interests us – μ , the average number of precursor cells. In addition, it can be represented graphically, providing a straight line in a semilogarithmic plot. In other words, the negative logarithm of the fraction of nonresponding (negative) cultures is linearly proportional to the mean number of precursors per culture. The resulting straight line has two uses. First, it allows the estimation of frequency by a variety of methods. Second, it acts as a sort of internal control to check that the system is measuring the activity of a single limiting cell type. A straight line means a single-hit curve, which means that only a single cell type is limiting (the pCTL). Any deviations from linearity determined by use of appropriate statistical methods would invalidate that starting assumption, confound the estimate of frequency, and preclude any further dependent analyses.

In the semilog plot in Figure 1, we could apply statistical methods to test the goodness of fit of the data points with the single-hit Poisson model by calculating χ^2 statistics and confidence intervals for the slope. If we assume that the line drawn in the figure is the best-fit line, then we can make a reasonable estimate of frequency from the plot by interpolating at 37% of negative cultures. This is best understood by substituting $\mu = 1$ in the zero term of the Poisson formula (1). We then derive

$$F_0 = e^{-1}$$

$$\text{i.e. } F_0 = 1/e = 0.37 = 37\%$$

There are more sophisticated ways of estimating frequency, and the reader is referred to Taswell. From the example shown here, interpolation at 0.37 reveals a frequency of pCTL of $1/2500$ or 4×10^{-4} .

What may be learned?

The LDA approach is now widely used to estimate precursor frequencies for a wide range of immunological responses (T cell growth, cytokine secretion, helper T cells, pCTLs, B cells at different stages of ontogeny, etc.). It can be manipulated to define the absolute frequency as elicited by the strongest stimuli known, and the operational frequency, i.e. that actually used in the immune response. It can be used to study changes in functional precursors in tolerance (see Desaynard and Waldmann; Good and Nossal) and after immunization.

From the basic frequency data, one can design further, more revealing biological experiments dealing with cell-cell interactions. For example, the first evidence that T cells and B cells have to contact each other to collaborate arose when it was shown that a single T cell (from LDA) could only collaborate with

one of many B cells offered to it. A modification of the procedure termed 'partition analysis' has allowed the investigation of T cells with inhibitory (suppressive) properties that are contained within a population of cells with helper properties.

In vivo, LDA can address a wide range of biological questions of precursor to product relationships. One particularly good example is the estimation of how many T stem cells are required to colonize a thymus lobe.

LINKAGE DISEQUILIBRIUM

Mary Ann Robinson, Laboratory of Immunogenetics, National Institutes of Health, Maryland, USA

Linkage disequilibrium is an important concept in genetic studies that aims to identify and/or localize genes related to disease susceptibility. The term linkage disequilibrium is commonly used to indicate that two genes are physically linked, however, the strict definition of the term does not specify close genetic linkage. Linkage disequilibrium is defined as the difference between the observed frequency of a particular combination of alleles at two loci and the frequency expected for random association. This is based on the assumption that, given sufficient evol-

utionary time, the occurrence of random recombination events will result in an equilibrium distribution of alleles at each locus. Thus, the frequency of a particular allele at a given locus will be independent of alleles at other linked loci.

In immunology, the term linkage disequilibrium is often encountered in studies of the HLA complex. The HLA gene complex consists of multiple highly polymorphic loci. Linkage disequilibrium (Δ) is most simply calculated using the equation:

$$\Delta(\%) = (F_{obs} - pq) \times 100$$

where p is the frequency of allele 'a' at locus 1, q is the frequency of allele 'b' at locus 2, and F_{obs} is the observed frequency of alleles 'a' and 'b' occurring together.

Taking a sample population where the gene frequencies of HLA-B8 and HLA-DR3 are 9 and 10% respectively, random recombination of HLA-B8 and HLA-DR3 would result in their presence in the same haplotype at a frequency of 0.9%. However, the observed frequency of HLA-B8/DR3 positive haplotypes is 7%, giving a linkage disequilibrium of 6.1%. Thus HLA-B8 and HLA-DR3 occur together in a haplotype in this population far more frequently than expected. Similar examples of linkage disequilibrium have been observed for alleles of HLA genes in every population studied; the specific alleles involved vary in different populations.

Many diseases have been associated with, or linked to, genes encoded within the HLA gene complex; however, the association between an HLA allele and a given disease is rarely absolute. Therefore, the observed association between a given HLA allele and a particular disease or functional characteristic may reflect some property of a gene closely linked to the tested locus, rather than a property of the locus itself.

Comparison of genetic and physical distances

Genetic distances between loci are determined by the frequency with which recombination events occur between the genes. Genetic distances are expressed in centimorgans (cM) where 1 cM corresponds to a recombination frequency of 1%. It is generally assumed that homologous recombination events can occur at any point in the DNA sequence and therefore genetic distances reflect physical distances. The ability to compare the relationship between genetic and physical distances more directly is now possible because of the technological advances in gene mapping allowing determination of the physical distance between two loci.

In humans, a genetic distance of 1 cM is calculated to be approximately 1200 kb (the average size of the human genome is about 2700 cM and contains approximately 3.3×10^6 kb of DNA). Within the HLA complex, there are regions where genetic and physical distances approximate calculated values and there are other regions where there are marked discrepancies. The physical distance (~1000 kb) between HLA-DR and HLA-B corresponds to the genetic distance (1 cM). By contrast, a recombination frequency of 3% (3 cM) has been observed between the HLA-DB and DQ subregions; these loci are

physically separated by only ~500 kb. Therefore, there is a significantly increased frequency of recombination between HLA-DP and HLA-DQ compared to the physical distance that separates them. These data imply that the properties of any given DNA segment may vary from those of another.

Use of linkage disequilibrium for gene mapping

Two genes may be found in linkage disequilibrium because they are physically close and recombination events do not occur frequently between them, thus linkage disequilibrium analyses have been used in gene mapping studies. Experimental approaches that make use of linkage disequilibrium have been successful in strengthening traditionally performed linkage analyses, particularly those involving genes with few alleles. Certain genes of interest for their role in a particular disease may not be highly polymorphic in a population, therefore the number of informative crosses available for examination may be limited.

In addition to close physical linkage, there are other reasons why two genes may be found in linkage disequilibrium. Two populations with distinct traits may have merged recently. Associations between alleles or traits may be apparent because insufficient time has passed for the genes to segregate randomly. Alternatively, there may be functional interactions between the products of two different loci that depend upon allelic differences. There may be a selective advantage to the co-inheritance of particular alleles of linked loci. The consequence of having a particular allele at one locus may not be observable unless there is a certain allele at another locus because of functional interactions between their products.

Impact of linkage disequilibrium on studies of the HLA complex

Regardless of the basis for linkage disequilibrium, it has an important impact upon analyses of HLA antigens in functional and disease association studies. A historical review of the HLA antigens found to be associated with certain diseases illustrates this point. As new loci within the HLA complex were identified, associations with allelic variants of these new loci in linkage disequilibrium were shown to be stronger than previously observed associations. The number of genes mapping to the HLA complex continues to increase. Due to linkage disequilibrium, functional associations with allelic variants of the newly defined loci may be stronger than those observed with previously characterized loci.

While the HLA gene complex provides the best known examples of linkage disequilibrium, this phenomenon is not limited to HLA. Linkage disequilibrium may also be a consideration when examining other gene complexes encoding immunologically relevant molecules. For example, the immunoglobulin heavy chain and T cell receptor and gene complexes are composed of linked gene segments that show allelic variations. Allotype markers (Gm) for the constant region of immunoglobulin G (IgG) heavy chain are inherited as fixed combinations or haplotypes that have been used as markers for various populations. The stability of Gm haplotypes suggests that linkage disequilibrium may be operative. In contrast, available information on the T cell receptor α and β chain gene complexes suggest that linkage disequilibrium is not a major determinant. Considering the relative physical sizes of T cell receptor α and β gene

complexes, there is extensive heterogeneity observed in the combination of markers present in haplotypes, suggesting that recombination has occurred frequently within the T cell receptor gene complexes.

LIPOSOMES

N van Rooijen, Cell Biology and Immunology, Medical Faculty of Vrije University, Amsterdam, The Netherlands

Liposomes are artificially prepared spheres consisting of concentric phospholipid bilayers separated by aqueous compartments. They form when amphipathic phospholipid molecules are dispersed in an aqueous solution. The phospholipids tend to find a conformation in which their hydrophobic fatty acid chains are prevented from direct contact with the water molecules. For that reason, phospholipid bilayers are formed, of which both outer parts are made up of the hydrophilic head groups, whereas the hydrophobic fatty acid chains are located directly opposite to each other and form the inner part of the bilayer (Figure 1).

Part of the aqueous solution, together with hydrophilic molecules dissolved in it will be encapsulated during the formation of the liposomes, whereas lipophilic molecules may be associated with the phospholipid bilayers. Amphipathic molecules, such as the phospholipids themselves, or conjugates made up of a phospholipid molecule and a hydrophilic molecule, attempt to find a conformation with their hydrophobic parts inserted in the bilayers and their hydrophilic parts extended either in the aqueous compartments or on the outer surface of the liposomes.

Because liposomes are biodegradable and may be composed of natural, nontoxic and immunologically inert phospholipid molecules, they have been sug-

gested as promising carriers of drugs. Since liposomes may serve as an immunoadjuvant with respect to encapsulated and surface-associated antigens, they have also been proposed as antigen carriers for application in vaccines.

Different liposomes for different applications

Liposomes can be prepared according to different methods. They may vary in their dimensions, composition (different phospholipids and cholesterol contents), charge (resulting from the charges of the composing phospholipids), and structure (multilamellar liposomes consisting of several concentric bilayers, separated by aqueous compartments or unilamellar liposomes, consisting of only one phospholipid bilayer surrounding one aqueous compartment). For a detailed description of liposome technology and chemistry, the reader is referred to Gregoriadis (1993, see Further reading).

The *in vivo* distribution of liposomes is strongly influenced by their characteristics. Targeting of liposome-encapsulated drugs to particular cells or tissues can be achieved by covalent attachment of monoclonal antibodies, or other appropriate proteins, to the outer surface of the liposomes. One possible approach to the preparation of such *immunolipo-*

Figure 1 Schematic representation of phosphatidylcholine liposomes and their possible association with antigen molecules.

somes is to incorporate the phospholipid molecule phosphatidylethanolamine in the phospholipid bilayers. This molecule can be covalently coupled to protein molecules by using their amino groups.

Phagocytosis forms the natural fate of the bulk of normal liposomes once they are administered into mammals. As a consequence, liposome-mediated modulation of macrophage function is one of the *in vivo* applications of liposomes. Liposome-encapsulated immunomodulatory molecules such as muramyl dipeptide (MDP) and muramyl tripeptide (MPT) can be used to activate macrophages, which then are able to eliminate metastatic tumor cells (e.g. in the liver) and show an increased capability to eliminate various microorganisms. It is not known whether the activated macrophages directly kill these cells and microorganisms or if their influence is mediated by other cells such as natural killer (NK) cells.

In contrast, some liposome-encapsulated drugs can be used to reduce macrophage activity or even to deplete macrophages completely from tissues or organs. This approach is increasingly chosen for studies aimed at unravelling macrophage functions *in vivo*.

When liposomes are chosen to serve as a depot for drugs (storage and gradual release) or when liposomes are intended for targeting of drugs to non-

phagocytic cells, uptake and clearance by macrophages can be reduced or even avoided by using liposomes with long half-lives in the circulation. Such *long circulating liposomes* can be prepared by coating liposomes with polyethylene glycol polymers or other molecules which inhibit opsonization of the liposomes.

Cationic liposomes can be prepared by the incorporation of cationic phospholipids in the bilayers. This allows a high-yield DNA incorporation and for this reason such liposomes may be more suitable for gene and antisense therapy. *pH-sensitive liposomes*, which destabilize and become fusion-active at mildly acidic pH, may be more suitable for delivery of encapsulated molecules into the cytoplasm of the target cells. Normally, the bulk of liposomes together with their encapsulated material will enter the lysosomal pathway, where it will be exposed to a large panel of lytic enzymes. It is a matter of course that combination of various liposomal features may lead to a product which is even better able to meet the needs of, for example, specific targeting or gene therapy. So, *long circulating immunoliposomes*, which are better able to avoid the cells of the mononuclear phagocyte system, are undoubtedly better in targeting encapsulated molecules to nonphagocytic cells. Also, *pH-sensitive cationic liposomes* may be expected to be better DNA carriers for gene therapy.

The latter liposomes allow a high-yield DNA incorporation due to their positive charge while their pH-dependent behavior promotes their fusion with endosomes, facilitating release of DNA into the cytoplasm.

Liposomes as antigen carriers

Liposomes may act both as carriers for haptens and as an immunoadjuvant for complete antigens. Haptenated liposomes induce a hapten-specific humoral immunoglobulin M (IgM) immune response without the generation of immunological memory. An IgG response is not detected after primary or secondary immunization with haptenated liposomes, and in addition mice depleted of, or deficient in T lymphocytes are able to respond to haptenated liposomes. Thus, haptenated liposomes are T cell-independent (TI) antigens. TI antigens are further divided into two types: TI-1 and TI-2. TI-2 antigens activate B lymphocytes from all the normal mouse strains except those of CBA/N, which carry an X-linked immune defect, and the immature B cells from neonatal mice of all strains. TI-1 antigens, having intrinsic mitogenic properties, stimulate B cells of all mouse strains, including those with the X-linked immune defect. It appears that CBA/N mice respond to haptenated liposomes, and for this reason these antigens are considered TI-1 antigens. However, unlike other known TI-1 antigens, they appear to be nonmitogenic in mice.

In contrast to haptenated liposomes, liposome-associated protein antigens elicit an IgG response in addition to the preceding IgM response, generate immunological memory, and behave as real T cell-dependent antigens. The response is strongly enhanced when the antigen is given in a liposome-associated form compared to free in solution. Antigens can be associated with liposomes either by encapsulation (masked antigenic epitopes) or by linking to their surfaces (exposed antigenic epitopes; see Figure 1). Surface exposition can be achieved by a number of methods for covalent attachment of the antigen to one of the phospholipids used for preparation of the liposomes or by nonspecific adsorption of hydrophobic antigens to the phospholipid bilayers. Antigens can also be entrapped in the liposomes when dissolved in the aqueous solution used for preparation of the liposomes. For most antigens, the latter procedure will result in liposomes with antigen entrapped in their aqueous compartments as well as exposed on their outer surfaces. The ratio between entrapped and exposed antigen may vary to a large extent and will depend on the characteristics of both the antigen, e.g. the presence and distribution

of hydrophobic groups, and the liposomes. It has been demonstrated that encapsulated antigens as well as surface exposed antigens induce both IgM and IgG antibodies. However entrapped antigens tend to stimulate a stronger IgG response, whereas surface exposed antigens tend to stimulate a stronger IgM response against the same antigen.

Liposomes have also been found to be efficacious antigen carriers for the induction of cytotoxic T lymphocytic (CTL) responses. pH-sensitive liposomes are especially able to elicit strong CTL responses. It is postulated that their efficacy in the induction of CTL responses depends on the fact that they are able to deliver the encapsulated antigen into the right intracellular compartment of the antigen-presenting cell (APC).

Dendritic cells, and not macrophages, are generally believed to be the major APC responsible for processing antigens and their presentation to T lymphocytes. This is in line with the observation that an enhanced antibody response is elicited when macrophages are selectively depleted prior to administration of soluble antigens. By competing with dendritic cells for the antigen molecules, macrophages actually reduce the amount of antigen which is available for dendritic cells. However, when large particulate antigens such as red blood cells (RBCs) or liposome-encapsulated antigens are injected, antibody responses are strongly reduced when macrophage depletion precedes antigen administration. Thus, macrophages play a crucial role in the induction of antibody responses against such large particulate antigens. Evidence is also accumulating that macrophages play a role in the induction of CTL responses against liposome-encapsulated antigens. Selective depletion of macrophages by a liposome based 'suicide' approach (see later) blocks the secondary CTL response induced by consecutively administered liposomal antigen. Since it is known that dendritic cell functions are not affected by this method of macrophage depletion, it would appear that macrophages are involved in the induction of CTL responses against liposome-encapsulated antigens.

One of the main advantages of liposomes as an immunoadjuvant is that they are biodegradable. They are ingested by macrophages which consecutively digest the phospholipid bilayers using their lysosomal phospholipases. As mentioned before, it is probable that liposome-mediated targeting of antigens to macrophages forms part of the mechanism of the immunoadjuvant activity of liposomes. Another important advantage of liposomes as an immunoadjuvant is that they may be composed of phospholipids (e.g. phosphatidylcholine) that are nontoxic in the doses used. Liposomes may even diminish tox-

icity of the associated antigens. It has been shown that after attachment of cholera toxin to liposomes containing ganglioside GM1, toxicity of the toxin was eliminated whereas immunogenicity was enhanced. Also the toxicity of lipopolysaccharide (LPS) incorporated with liposomes appeared to be reduced when compared to free LPS. It is not surprising that phospholipids, which form the basic matrix of all cell membranes, are not very immunogenic themselves. Although liposomes may serve as carriers for haptens and as an immunoadjuvant for protein antigens, antibodies against their phospholipid component are not elicited, unless LPS or LPS-derived lipid A is inserted in these bilayers. It has been shown by Alving and coworkers that incorporation of LPS or lipid A greatly enhances the adjuvant activity of liposomes, but, in addition, antibodies to the liposomal phospholipids and even to liposomal cholesterol can also be induced. There is some evidence that these phospholipid-specific antibodies are produced by a distinct lineage of B cells (CD5⁺, B-1 cells), which might also be involved in autoimmune reactions.

Liposome-based immunoassays

Several liposome-based immunoassays have been developed to detect immune-related compounds or analytes of interest. The aqueous compartments of liposomes can be used to carry various reporter molecules and the so-called immunoliposome assays may offer distinct advantages over existing immunoassays depending on the nature of the intended assay. A wide variety of immunoliposome assays have been developed with different approaches and sensitivities. Antibody as well as antigen concentrations can be determined due to the fact that, in the presence of specific antibody, antigen- or hapten-bearing liposomes can fix complement, which in turn may result in the lysis of such liposomes by activated complement and the consecutive release of the encapsulated markers. Based on the finding that antigen-specific lysis can be inhibited by addition of soluble antigen to compete for the binding of antibody to the liposome-exposed antigen, a number of inhibition assays have been developed.

Liposomes for manipulation of macrophage functions

The selective targeting of immunomodulators to appropriate sites of action is an integral and important component of immunotherapy for infectious diseases and cancer. Most attempts to target liposomes to solid tumors have been disappointing

because the phospholipid vesicles are unable to reach organ parenchyma, since they are not able to cross the barriers formed by capillary walls. Also, they are rapidly endocytosed by phagocytic cells. However, taking advantage of this natural fate of liposomes to target immunomodulators to cells of the mononuclear phagocyte system, Fidler and colleagues were able to activate these cells to a tumoricidal or virocidal state. Systemic administration of liposomes containing various immunomodulators has been shown to bring about regression of lymph node, lung and liver metastases, and dramatic prophylaxis of viral infections in rodents.

Macrophages perform a wide variety of functional activities in immune reactions. They have an important role in the clearance of immune complexes and apoptotic T and B lymphocytes and they are involved in processing of particulate antigens. In addition they play a crucial role in the differentiation of several nonphagocytic cells and in the regulation of their functions. These latter roles are dependent upon the production of a number of cytokines and other soluble mediators by the macrophages. Recent studies have shown that, for example, in the liver, macrophages (Kupffer cells) are responsible for the bulk of all lipopolysaccharide-induced interleukin 1 β (IL-1 β), IL-6, IL-10 and IL-12 mRNA expression. Macrophages form a heterogeneous cell population. In the spleen for instance, red pulp macrophages, marginal zone macrophages, marginal metallophilic macrophages, white pulp macrophages and tingible body macrophages show a compartment-specific localization pattern. In addition, they can be distinguished by different surface markers, a different morphology and by differences in their functional specialization.

Selective *in vivo* depletion of macrophages is a widely accepted approach used to investigate whether macrophages are involved in any particular biomedical process. Since the effects of the usual methods for macrophage depletion, such as treatment with silica, carrageenan, antimacrophage antibodies etc. were neither selective nor complete, we developed a new approach, based on the liposome-mediated intraphagocytic delivery and accumulation of the bisphosphonate clodronate. Macrophages ingest the liposome-encapsulated clodronate and then disrupt the phospholipid bilayers using their lysosomal phospholipases (see Figure 2). The encapsulated clodronate is then released within the cell and since clodronate molecules do not easily escape from living cells, the drug is accumulated intracellularly. Finally, the cell death programme is activated, leading to elimination of the cell by apoptosis. Using this so-called liposome-mediated macrophage 'suicide'

Figure 2 Liposomes, encapsulating clodronate or other water-soluble molecules (squares) in their aqueous compartments, are ingested by macrophages. After fusion of the liposome-containing endosome with lysosomes (L) containing phospholipases (arrowheads), the latter disrupt the phospholipid bilayers of the liposome. The more the concentric bilayers of the liposome are disrupted, the more the encapsulated molecules are released within the cell. N, nucleus.

approach, it has been established for instance, that alveolar macrophages actively suppress the function of dendritic cells in the lung, that liver macrophages play a role in the differentiation of liver-specific NK cells and that testis macrophages play a role in the differentiation of Leydig cells.

It is anticipated that, apart from effects mediated by physical depletion of macrophages from tissues, encapsulated drugs (in sublethal doses for macrophages) may also prove to be useful in the

transient suppression of macrophage activity. This may be particularly relevant to the role of macrophages in the induction of inflammation, since the macrophage-derived cytokines IL-1 and tumor necrosis factor α (TNF α) appear to play a crucial role in the induction of various inflammatory reactions.

LISTERIA, INFECTION AND IMMUNITY

C J Czuprynski, Department of Pathobiological Sciences, School of Veterinary Medicine, University of Wisconsin, USA

Characteristics of the organism and its antigens

The genus *Listeria* contains seven species, only two of which, *L. monocytogenes* and *L. ivanovii*, are pathogenic. The former is by far the principal pathogen of the groups and will be described in this article. It is widespread in the environment and has been isolated as a commensal and a pathogen from a wide variety of vertebrate species. It causes abortion, meningitis and septicemia in human beings, and encephalitis, abortion and mastitis in ruminants. The usual portal of entry is thought to be the gastrointestinal

tract. This latter point has been amply demonstrated by several large outbreaks, and numerous sporadic cases, of listeriosis in people who ingested *Listeria*-contaminated food products. Listeriosis causes considerable morbidity and a relatively high mortality rate, particularly for the fetus of infected pregnant women and for immunosuppressed adults.

L. monocytogenes is a gram-positive, nonsporulating, β -hemolytic, facultatively anaerobic, catalase-positive rod. It possesses the ability to multiply at 3–45°C and, under some circumstances, to survive short periods at temperatures of 60°C or greater. Organisms grown at room or refrigeration tempera-

ture have multiple flagella and are motile, whereas those grown at 37°C have few flagella and are non-motile. The ability of *L. monocytogenes* to multiply (albeit slowly) at 4°C can be used as an enrichment technique for its isolation from clinical specimens.

Both somatic and flagellar antigens are used to serotype *L. monocytogenes*; nearly all human and animal infections involve serotypes 4b, 1/2b and 1/2a. SDS-PAGE analysis reveals a number of protein bands with T cell-activating and B cell-mitogenic activity. Organisms grown at 20°C produce abundant amounts of a 29 kDa protein that is flagellin. The cell wall contains abundant teichoic acids and lipoteichoic acids. Virulent *L. monocytogenes* produce an extracellular 58 kDa thiol-activated hemolysin that is immunogenic for both T and B cells. Humoral and cellular immune responses against other virulence determinants (internalin, actA, p60) have also been reported.

Immune responses of the host

Because of its relative convenience, reproducibility and safety, murine listeriosis has been widely used as a model for investigating protective cellular immunity to facultative intracellular pathogens. It had been thought that the organism resided principally within macrophages, however more recent data suggest that large numbers of listeriae reside and multiply within hepatocytes in the infected host. Innate resistance to listeriosis in mice is controlled principally by the Lr1 locus on chromosome 2, which is linked with the Hc locus that regulates production of the fifth component of complement. *Listeria*-resistant strains of mice recruit greater numbers of inflammatory phagocytes in response to injection of listeriae and various sterile irritants than do susceptible strains of mice. *Listeria*-immunized mice recruit a greater number of inflammatory phagocytes in response to injected listeriae than do nonimmunized controls. Blood and inflammatory neutrophils and mononuclear phagocytes from several mammalian species kill *L. monocytogenes* *in vitro*, whereas resident macrophages have limited antilisterial activity. Some investigators have reported enhanced antilisterial activity for macrophages isolated from immunized mice, or activated *in vitro* with interferon γ (IFN γ). Other researchers found that macrophages activated *in vivo* or *in vitro* are no better able to kill listeriae *in vitro* than are macrophages elicited by nonspecific inflammatory agents. Both oxygen-dependent and independent bactericidal mechanisms may contribute to killing of listeriae. Some studies demonstrated the importance of reactive nitrogen intermediates for

resistance *in vivo*, or macrophage anti-*Listeria* activity *in vitro*, while others demonstrated no effect.

Host defense against *Listeria* is quite complex, involving a number of cell types and mediators (Figure 1). Depletion of CD4⁺, CD8⁺, TCR $\alpha\beta$ ⁺ or TCR $\gamma\delta$ ⁺ cells results in a more severe infection, but the animals generally recover and eradicate the listeriae from their tissues. In contrast, mice depleted of both TCR $\alpha\beta$ ⁺ and TCR $\gamma\delta$ ⁺ cells demonstrate profoundly reduced resistance, as do mice completely depleted of Thy-1.2⁺ cells. These findings suggest that T cell-mediated immunity is important, but not the sole factor, in resistance to listeriosis. This is underscored by earlier observations that experimentally infected athymic nude mice, or SCID mice, are unable to completely eliminate the *L. monocytogenes* from their tissues. Animals that have cleared a sublethal *L. monocytogenes* infection are resistant to reinfection with 1000-fold greater numbers of *L. monocytogenes* than would prove fatal for naive mice. One can transfer resistance to naive recipient mice with T lymphocytes from the spleen, or other tissues, of immunized mice.

Other cells, particularly neutrophils, make important contributions to anti-*Listeria* resistance. Mice treated with monoclonal antibodies that either prevent extravasation of neutrophils, or deplete them of mature granulocytes, succumb to infection with low numbers of *L. monocytogenes* that are easily eliminated by control mice. Granulocytes interact directly with *Listeria*-infected hepatocytes, and appear to either lyse infected cells or release mediators (e.g. tumor necrosis factor α , TNF α) that make the hepatocytes less permissive for intracellular listerial multiplication. Natural killer (NK) cells have also been implicated in resistance to listeriosis, perhaps via their ability to rapidly release large amounts of IFN γ that can restrict listerial multiplication in hepatocytes and macrophages.

Cytotoxic T cells are activated by *L. monocytogenes* as a result of its intracellular replication cycle, in which it multiplies freely within the cytoplasm of macrophages and other cells. *L. monocytogenes* antigens are thus processed and presented on the cell surface with class I antigens that activate, and serve as targets for, cytotoxic T cells. A series of elegant investigations have delineated the immunodominant portions of *L. monocytogenes* virulence molecules (e.g. hemolysin) and provided a powerful model for studying the specificity and regulation of cytotoxic cell-target cell interactions. The relative importance of cytotoxic cells in resistance to listeriosis is unclear, however, as depletion of CD8⁺ cells reduces, but does not eliminate, resistance to infection.

L. monocytogenes infection results in rapid

Figure 1 An overview of some of the cells and cytokines likely to be involved in host defense against *L. monocytogenes*. Mφ, macrophage; PMN, polymorphonuclear leukocyte. (Illustration by P.W. Yu.)

expression of IFN γ , IL-1 β , TNF α , granulocyte-macrophage colony-stimulating factor (GM-CSF), and other cytokines. IFN γ and TNF α appear to be perhaps the most important endogenous cytokines for resistance to listeriosis. Resistance to *L. monocytogenes* infection is consistent with the T_H1–T_H2 cytokine paradigm, as IFN γ (T_H1) is required for resistance, and both interleukin 4 (IL-4) and IL-10 (T_H2) impair resistance. The pivotal role of macrophage production of IL-12 in determining whether a T_H1 or T_H2 cytokine response will predominate was first delineated in an *L. monocytogenes* infection model.

Administration of a wide array of recombinant cytokines, particularly those that potentiate the inflammatory response (e.g. IFN γ , TNF α , IL-1 β , IL-12), enhance resistance to *L. monocytogenes* infection.

Evasive strategies of the organism

L. monocytogenes can invade and multiply within mononuclear phagocytes, hepatocytes and epithelial cells (Figure 2). It produces a series of virulence factors that enable it to invade cells, multiply intracellularly, and directly invade adjacent cells. This results in foci of infection that can be readily demonstrated by histopathology. These virulence determinants are positively regulated in a coordinated manner by the product of the *prfA* gene. A surface protein, called internalin, facilitates adherence and invasion of mammalian cells via interaction with E-cadherin (Figure 2, step A). Another *L. monocytogenes* protein (p60), which can be found on the bacterial surface or secreted into the culture medium, also affects interaction with mammalian cells. Once it invades a mammalian cell, *L. monocytogenes* escapes from the

Figure 2 Stages involved in the invasion and multiplication of *L. monocytogenes*. See text for details.

membrane-bound phagosome by the action of its hemolysin and two phospholipases C, one of which has broad activity and the other of which is phosphatidylinositol specific (step B). The listeriae then multiply freely within the cytoplasm (step C) and express a surface protein, called actA, that serves as a nucleation point for the attachment of actin filaments (step D). This occurs in a unidirectional manner such that new actin subunits are continually placed on the surface of the bacterium, resulting in formation of a long (up to 40 μm) actin tail. These actin tails can propel *L. monocytogenes* at speeds of up to 1 $\mu\text{m s}^{-1}$, driving some of them through the cytoplasmic membrane of the original cell and into the cytoplasm of an adjacent cell (step E). The listeriae then escape from the double membrane-bound phagosome in which they find themselves (step F), and repeat the replication cycle (step G). Cellular and humoral immune responses to the hemolysin, internalin, and actA have been demonstrated. Which of these responses is most important for restricting the multiplication of the organism is not clear.

Vaccines

Vaccination of experimental animals is typically achieved by injection of a sublethal dose of viable listeriae. Surviving mice are highly resistant to rechallenge for several months, and then resistance gradually wanes. Infection with other facultative intracellular pathogens may induce nonspecific resistance to listeriosis and vice versa. Injection of killed listeriae generally does not confer substantial immunity, although vaccination with subunits of *L. monocytogenes* in adjuvant has been reported to provide limited protection against experimental challenge. Immunization with large numbers of avirulent *L. monocytogenes*, or with other *Listeria* species, may induce a transient increase in resistance. Use of atten-

uated vaccines in sheep has been reported to lower the incidence of spontaneous listeriosis.

Other strategies have been shown to transiently increase anti-*Listeria* resistance in mice. Various biological response modifiers (e.g. killed *Lactobacillus casei*, trehalose dimycolate, muramyl dipeptide) have been reported to stimulate anti-*Listeria* resistance, perhaps via release of various cytokines. Prophylactic administration of a number of recombinant cytokines (e.g. IFN γ , IFN β , IL-1 α , IL-2, TNF α , GM-CSF and others) afford short-lived enhancement of anti-*Listeria* resistance. The ability of *L. monocytogenes* to multiply freely in the cytoplasm of infected cells has been exploited as a vehicle for eliciting a class I major histocompatibility complex (MHC)-dependent cytotoxic T cell response against other antigens. Recombinant *L. monocytogenes* has been used as a vaccine vector to elicit protective immunity against experimental infection with several viruses, and against tumor cells expressing viral antigens.

LYMPHATIC SYSTEM

Joseph G Hall, Formerly of Royal Marsden Hospital at University College of London Medical School, London, UK

The lymphatic system is an integral part of the blood vascular system of vertebrates, but in mammals it also plays a crucial part in the transport and distribution of antigens, antibodies and immunologically competent cells. Similarly, it is important in the dissemination of tumor cells and in immune reactions to them.

The word 'lymph' simply means 'a clear fluid' and its existence as an internal body fluid, distinct from blood and other humors, was appreciated by physicians of the early Mediterranean civilizations. A scientific understanding of the composition and formation of lymph only became possible during the last part of the nineteenth century and it was not until the beginning of the twentieth century that Starling gave the subject a sound physiological basis.

In any animal with a substantial blood pressure, fluid and some plasma proteins are forced to leak continually through the walls of the blood capillaries. The primary function of the lymphatic system is to collect this proteinaceous fluid and return it to the blood vascular system, and thus maintain the volume of the circulating blood plasma. The lymphatic system thus transports extravascular macromolecules and it follows that it plays a major part in the transport and distribution of antigenic material. In mammals, the lymphatic vessels that convey the lymph from the peripheral tissues back to the great veins at the root of the neck are interrupted at various points by secondary lymphoid organs, the lymph nodes.

These are richly vascularized structures composed of a meshwork of collagen fibers which are covered with reticular cells. In addition, they are the site of the large-scale extravasation of lymphocytes. The reticular cells enable the node to act as a filter and to arrest much antigenic material that is in the lymph, while the incoming B and T lymphocytes from the blood react to the antigen and transform respectively into antibody-forming cells and activated helper or cytotoxic lymphocytes. Many of these are discharged into the lymph efferent from the nodes and so become distributed systematically.

Methodology

Most of what is known about the function of the lymphatic system has come from experimental work on animals. Although there were some notable experiments in the eighteenth, nineteenth and early twentieth centuries, the procedures were not easy until small, flexible, plastic cannulae became available in the mid-twentieth century. This made it possible to cannulate the major lymph trunks, such as the thoracic duct in rats, guinea pigs, and even mice, and to collect substantial volumes of lymph.

A major problem with this procedure was that it required relatively deep anesthesia as well as the postoperative restraint of the animals in specially designed cages. These factors induce major perturbations in the function of the blood vascular system and the levels of the adrenocortical hormones. Also,

in the ensuing days, the loss to the animals of substantial amounts of fluid, protein, electrolytes and cells rapidly produce a state of metabolic chaos unless elaborate facilities are at hand to make good the deficits at physiological rates. Although such preparations can be a useful source of lymph cells, their value as physiological models is limited.

In the early 1960s Professor Bede Morris of the Australian National University initiated research into the lymphatic physiology of ruminant species, particularly sheep. The latter are docile animals that make no attempt to interfere with cannulae that have been inserted into them; they need no restraint and can be kept in ordinary pens to which they are accustomed. Also, the cannulation of a single peripheral lymph duct causes an insignificant metabolic deficit so that lymph from individual organs can be collected for periods of weeks from unanesthetized animals under physiological conditions. Because of the structure of the ovine placenta, it is even possible to cannulate lymphatic vessels of fetuses *in utero*. These types of preparations have yielded much useful and novel information, and will probably continue to do so. However, the risks of extrapolating data from a single species should not be overlooked.

Some useful data have been obtained from humans but ethical and technical difficulties have prevented systematic studies.

It may be worth noting here that while lymph always contains some lymphocytes, and may occasionally contain all other classes of blood leukocytes as well as some red cells, it never contains platelets. It does, however, contain fibrinogen and will clot unless anticoagulants are added to the containers into which it is collected.

The formation and composition of lymph

Lymph begins as an ultrafiltrate of blood at the arteriolar, high-pressure region of the capillary. Towards the venular end of the capillary, the hydrostatic pressure of the blood is much lower and this, together with the osmotic 'pull' of the blood plasma proteins, allows some of the water and crystalloids of the ultrafiltrate to be reabsorbed (Figure 1). However, the protein component of the ultrafiltrate is not reabsorbed and remains in the tissue spaces until it is carried away in the lymph. By virtue of its own colloid osmotic pressure (sometimes referred to as the 'oncotic' pressure) the protein retains some water and crystalloids with it, and it is this somewhat concentrated ultrafiltrate that constitutes the tissue fluid proper, which is the fluid that enters the peripheral lymphatics.

The composition of the tissue fluid varies some-

what from tissue to tissue, and with the level of activity, and hence blood pressure, of the individual. In general terms, the total protein concentration of the tissue fluid is about 25–30% of that of the blood plasma. It contains the whole range of blood plasma proteins, but their relative concentrations are different from those of the blood. This is because the ultrafiltration process functions as a molecular sieve so that smaller molecules, such as albumin (66 kDa) pass through relatively easily, but immunoglobulin G (IgG) is less well represented (150–170 kDa), and the large IgM molecule (970 kDa) is present at a concentration less than 8% of the blood plasma value.

The physiological basis for ultrafiltration and molecular sieving is unknown. It is explained best by the 'Pappenheimer pore theory', which postulates that the capillary endothelium has the characteristics of a semipermeable membrane provided with 'pores' of graded sizes. The theory envisages that there are more small pores through which albumin can pass than large ones that allow the escape of, for example, IgM. However, the pore theory is really a mathematical abstraction used to explain experimental results and it was not meant to imply that obvious pores exist as observable microanatomical entities. The structural basis of the 'pores' is debatable. Some workers believe that they consist of transient gaps between endothelial cells. Others believe that the real ultrafiltration apparatus resides in the basement membrane which surrounds the outer surface of the capillary endothelium. It has also been proposed that the extravasation of fluid and protein is brought about by the transcytosis of endocytic vesicles that traffic across the cytoplasm of the endothelial cell. So far, there is really no satisfactory detailed explanation of the observation that the ease with which plasma proteins escape from the circulating blood, across the capillary wall and into the tissue fluid, is inversely proportional to their mean diffusion diameters.

Despite these conceptual difficulties, it is relatively easy to measure the permeability characteristics of a given capillary bed. This is done by injecting intravenously a dose of plasma protein, usually albumin, labeled with, for example, a radioisotope. Lymph is then collected from the region under study at appropriate intervals and compared with corresponding samples of venous blood plasma. When the amount of radioactivity per unit weight of protein in the lymph is equal to that in the blood, 'equilibration' is said to have occurred. The elapsed time between the initial injection and the equilibration is known as the 'equilibration time' and gives a relative measure of the permeability of the particular capillary bed.

For most mammalian somatic tissues, the equili-

Figure 1 The principles of lymph formation. The high hydrostatic pressure at the arterial end of the capillary forces proteinaceous fluid through the capillary wall. At the venular end the hydrostatic pressure is low, and the colloid osmotic pressure of the plasma proteins causes the reabsorption of water, electrolytes and crystalloids. The protein cannot be reabsorbed and together with some water and solutes, it is drained away by the lymph. Note that the diagram is not to scale and in reality the diameter of the capillary just permits the passage of a red cell, while the larger white cells have to deform to pass through. This imposes a resistance to flow which helps to create the pressure drop between the arterial and venous ends of the capillary. NATO ASI series *Life Sciences*, vol 155. New York: Plenum Press.)

bration time for albumin is between 12 and 24 h, depending on the activity of the individual. There are, however, some major variations. For example, the endothelium of the portal sinusoids in the liver is fenestrated by ultrastructurally observable discontinuities. For this reason, there is no continuous barrier to impede the egress of the plasma proteins; the hepatic lymph plasma has a protein concentration almost as high as that of the blood, and the equilibration time is only 1–2 h.

At the other end of the scale is the central nervous system, which has no conventional lymphatic apparatus at all. The endothelial cells of the intracerebral capillaries are very tightly joined, so virtually no protein escapes. What little protein there is in the cerebrospinal fluid is provided by specialized tufts of vasculature in the choroid plexuses that lie on the floor of the ventricles. Nonetheless, there is a flow of fluid into the confines of the skull and an equivalent amount has to be removed to maintain the status quo.

Fluid is removed in two ways. First, small villous structures from the arachnoid membrane of the brain bulge into the main venous sinuses, and these arachnoid villi can be envisaged as a sort of private lymphatic system for the brain because they transmit excess fluid back into the venous blood. Second, some fluid tracks down the sheaths of the cranial nerves, particularly the olfactory nerves, and so gains entry into the nasal submucosae, where it is absorbed by conventional lymphatic vessels.

Fluid exchange in the lungs presents particular problems. The perfusion pressure is low, the blood pressure in the pulmonary arteries being much lower than in the arteries of the systemic circulation. Accordingly, in spite of the large blood flow, relatively little lymph is formed. Similarly, the low blood pressure makes the lung vasculature vulnerable to embolic phenomena. For example, white cells or tumor cells that are infused intravenously may be arrested temporarily in the lungs because there is not enough pressure to push them through the capillaries at the usual rate.

The movement and propulsion of lymph

Tissue fluid is formed continually, and this causes the tissue tension to rise. As it does so, fluid is forced into the collecting bulbs of the most peripheral lymphatic capillaries. These structures have a rather scanty basement membrane, to which the endothelial cells are loosely attached; these cells act as 'flap valves' which favor the entry, rather than the exit, of fluid. The confluence of lymphatic capillaries forms larger vessels which have a more definite structure. The

basement membrane is continuous and surrounded by coats of smooth muscle, and the vessels are provided with numerous bicuspid valves which prevent retrograde flow (see **Figure 1**). The muscular coats of the lymphatic vessels exhibit intrinsic rhythmic contractions; these generate pulse pressures of several mm Hg, and force the lymph in a central direction. The rate of pulsation of the lymphatic vessels increases in parallel with the pressure inside them, and so a mechanism exists for transporting the lymph at a rate proportional to its rate of formation.

The mechanisms that modulate the lymphatic pulse have yet to be defined accurately; the action of adrenergic nerves, and the local synthesis of prostaglandins and nitric oxide have all been proposed. However the contraction waves themselves seem to be an intrinsic response to the stretching of the muscle coats.

In considering the flow of lymph, it is necessary to distinguish critically between those factors that increase the formation of lymph, and those that actually move it. For example, when a limb is at rest, the blood flow is low and little lymph is formed, there is no fluid to distend the lymphatics and provoke a contraction wave in the larger lymphatic vessels, and so there is little observable lymph flow. If the limb is moved, either actively or passively, some residual tissue fluid is forced into the lymphatics and so promotes active contraction in the lymphatic vessels. Continued passive movements soon exhaust the supply of tissue fluid and lymph flow again becomes sluggish, whereas active movements promote greater blood flow, the formation of more tissue fluid, and thus a continuous flow of lymph.

Anatomical compartments

The lymph of mammals is classified as being peripheral, intermediate or central. Peripheral lymph is lymph which has not yet passed through a lymph node. Intermediate lymph is lymph contained in vessels between lymph nodes. Central lymph is lymph contained in the major lymph trunks like the intestinal, thoracic, right lymph duct or deep cervical duct. Central lymph does not pass through any lymph nodes before it enters the great veins at the root of the neck (**Figure 2**).

Peripheral lymph

True peripheral lymph has a very low content of white cells, usually well under 1000 mm⁻³. Most of these are small lymphocytes of which some 85% are T cells. However, peripheral lymph is distinguished by the presence of 'veiled' dendritic cells, which account for about 10% of the cellular content

(Figure 3). Their main function is probably the induction of T cell-mediated immunity.

Intermediate lymph

Intermediate lymph is populated by large numbers (up to $20\,000\text{ mm}^{-3}$) of small lymphocytes, some 75% of which are T cells. Nearly all of these are recirculating lymphocytes that have extravasated from specialized postcapillary venules in the node. In rodents and humans, these specialized venules are recognizable in histological sections because of their cuboidal or 'high' endothelium (high endothelial venules, HEV) between which extravasating lymphocytes may be identified. This high endothelium is not seen in the lymph nodes of ruminants or athymic rats, even though the recirculation of lymphocytes is taking place. Lymphocyte extravasation in sheep proceeds via paracortical venules in lymph nodes. The function of these venules appears to be analogous to HEV in nonruminant species.

Hardly any of the dendritic cells from peripheral lymph appear in intermediate lymph. The majority are retained by the first node to which the lymph stream carries them. In this context, it should be remembered that more deeply seated nodes will receive two sorts of afferent lymph. One will be lymphocyte-rich lymph efferent from more peripheral nodes; the other will be genuine hypocellular, peripheral lymph formed in the adjacent tissues.

The lymphatic system in the gut has a rather special organization. There is an abundant extravasation of lymphocytes in the wall of the gut. This occurs diffusely throughout the length of the intestine, but also in macroscopic aggregates of subepi-

thelial lymphoid follicles that occur at intervals along the antimesenteric aspect of the small gut. These structures, the Peyer's patches, are believed to provide the B and T cells necessary for inducing immune responses which result in the production of IgA, the principal immunoglobulin in the secretion which protects all mucosal surfaces. In ruminants, the ileal Peyer's patch is also the site at which immature B cells undergo proliferation and the genetic rearrangements that endow them with the potential for Ig synthesis. In all mammalian species, these special features endow peripheral intestinal lymph with a content of lymphocytes that is about 50 times greater than that of peripheral lymph from any other organ. The lymph also contains substantial numbers of dendritic cells and, in postnatal animals whose guts have been colonized by bacteria, significant numbers of immunoblasts are also present. The regional nodes of the gut – the mesenteric nodes – are thus perhaps unique in receiving a supply of hypercellular afferent lymph that is already immunologically activated to some degree. It may be, however, that the same applies to those cervical nodes which receive lymph from Waldeyer's ring (i.e. tonsils, adenoids, etc.) but direct evidence is lacking.

There are other noteworthy features of the intestinal lymphatic system. The intestine is the site of the absorption of fatty acids from the diet, and these are processed into minute fat globules – the chylomicra – by the enterocytes which then discharge them into the lymph and give it its characteristic milky appearance.

Central lymph

Central lymph is merely a conglomerate of all the intermediate lymph contained in the various lymphatics that unite to form the major lymph trunks. For the practical purposes of immunology, thoracic duct lymph is the most commonly collected example. It is as well to remember that the thoracic duct is the final common pathway of all lymph generated below the level of the diaphragm, and the majority of this is lymph from the intestine. In sheep, the small lymphocytes from intestinal lymph can be shown to recirculate preferentially through the gut, while those from nonintestinal lymph recirculate mainly through other tissues. At present there is no direct evidence that this distinction applies to humans and rodents. There is less uncertainty about the behavior of the large lymphocytes (immunoblasts) which are present in intestinal, and thus thoracic duct lymph. After being discharged into the blood they extravasate abundantly and rapidly in the lamina propria of the small gut. Many of them can be shown to transform into classical plasma cells which synthesize and

Figure 3 Phase-contrast photomicrograph (approximately $\times 1500$) of small lymphocytes and 'veiled' dendritic cells in peripheral lymph from the leg of a sheep.

secrete antibody. Much of this is of the IgA class; that which is not immediately secreted into the lumen of the gut is swept up into the intestinal lymphatics, conveyed to the blood and transported rapidly into the bile by the active transcytotic vesicles in the hepatocytes.

Transport of antigens

The intravenous injection of a dose of antigen may be experimentally convenient but it is rather unnatural. Apart from some arthropod-borne parasitic and viral diseases, secondary septicemia, etc., the presence in the blood vascular system of significant amounts of microbial antigens is fortunately a rare event. Most naturally occurring infections begin with the penetration into the tissue fluid, via the skin or mucosae, of invading microorganisms. In such cases, the exogenous material is swept up into the lymphatics and conveyed to the regional node. This mechanism is mimicked by injecting antigens either intradermally or subcutaneously.

A foreign soluble protein that finds its way into the tissue fluid will be conveyed almost quantitatively to the regional nodes. Unless pre-existing specific antibodies convert it into immune complexes, or unless it is a lectin or toxin that binds with high affinity to mammalian cells, very little of it will be retained in the node. Most of it will pass through the lymph nodes and enter the central lymph, and thus the blood. For this reason, many ordinary soluble proteins tend to be poorly immunogenic unless they are first aggregated and/or mixed with adjuvant. In the presence of specific antibody, the antigen will accumulate in germinal centers of lymphoid tissues, where it will be presented to B lymphocytes in the form of antigen-antibody complexes on follicular dendritic cells.

Particulate material such as bacteria and viruses tend to be filtered out of the lymph stream more efficiently by the phagocytes of the regional node. This is partly because particles are more susceptible to mechanical filtration, and partly because of the presence of 'natural' antibodies that can react with such materials. Of course, there are exceptions, such as certain pathogenic microorganisms which, almost by definition, are able to elude host defenses unless a state of specific immunity has been induced previously.

Antigens and cell traffic

The arrival at a lymph node, via its afferent lymphatics, of an immunogenic dose of antigen, sets in train an enormously complicated series of cellular

events. In the first 2–3 days after the antigenic stimulus, the output of recirculating lymphocytes in the efferent lymph increases about threefold from a basal level of some $3 \times 10^7 \text{ h}^{-1} \text{ g node weight}^{-1}$. This phase is generally regarded as a phase of 'recruitment' during which those lymphocytes with appropriate immunological specificity are selected from the larger numbers made available by increased blood flow through the node. The lymphocytes thus selected react to the antigens and cytokines present and transform into immunoblasts in the paracortex of the node. Some of these blast cells mature and carry out their various functions within the node itself, but others are discharged into the efferent lymph where, about 4 days after the initial stimulus, they may account for up to 30% of all the cells. These free-floating immunoblasts are able to colonize other lymphoid tissues to which the lymph, and later blood, may carry them. In this way, a state of systemic humoral and cell-mediated immunity may be established even when the antigen itself (which may be potentially pathogenic) remains localized in the node which first received it.

In most mammalian species, the antibodies and cells produced in a lymph node during an immune response are dependent absolutely on the lymphatic system for their initial transport. In pigs, however, the cells trafficking through lymph nodes are able to leave by direct entry into the intranodal blood vasculature. Consequently, there are few lymphocytes in the intermediate and central lymph of pigs. Such exceptions should alert us to the fact that facile generalizations about the behavior of lymphocytes and lymphatics can be misleading given that there are significant differences between mammalian species in the structure and function of the lymphatic apparatus.

LYMPH NODES

CE Grossi, National Institute for Cancer Research, University of Genoa, Genoa, Italy

PM Lydyard, Department of Immunology, University College London Medical School, London, UK

Lymph nodes are encapsulated organs ranging in size (in humans) from a few millimeters to more than a centimeter, and generally ovoid in shape. They are found as groups of nodules along the lymphatic vessels draining superficial areas of the skin or deep viscera. The bases of the limbs, the neck, the retroperitoneal areas in the pelvis and abdomen, and the mediastinum are sites especially rich in lymph nodes (Figure 1).

Lymph nodes are peripheral lymphoid organs colonized by bone marrow-derived B cells and thymus-derived T cells which seed into distinct zones of the lymphoid parenchyma. The organization of the lymph node must favor the interactions between antigens and lymphocytes equipped with specific antigen receptors. For this reason, lymph nodes contain numerous cells capable of processing and presenting antigens (macrophages, dendritic cells, interdigitating cells and veiled cells) and are continuously renewing their cell populations through active lymphocyte and accessory cell trafficking.

Both humoral and cell-mediated immune responses can occur in lymph nodes. Consequently, activated lymphocytes and T or B effector cells are frequently detected. Following an immune response to antigen, memory T or B cells are also generated which, similar to the unstimulated lymphocytes, are located in distinct zones of the lymph node.

Structure of the lymph node

A lymph node consists of capsule, reticulum, lymphoid tissue with lymphocytes, blood and nerve supplies (Figure 2).

The capsule is composed of dense collagenous connective tissue. It has a broad convex surface, and at one point, a deep indentation, the hilus. Afferent lymphatic vessels pass through the convex surface of the capsule and empty into the subcapsular (or marginal) sinus. One efferent lymphatic vessel leaves at the hilus where blood vessels and nerves enter and exit. Connective tissue projections of the capsule into the node are seen as the trabeculae.

The reticulum is a delicate meshwork enclosed by the capsule and trabeculae and consists of reticular cells and fibers. The reticular cells are large, branched fibroblasts which produce the reticular fibers.

Lymphocytes and other free cells lie in this meshwork and form the lymphoid tissue or lymph node parenchyma. Three distinct regions of the lymph node parenchyma extend from the capsule in towards the hilus. These are termed 'cortex', 'paracortex' and 'medulla'.

The cortex is largely occupied by lymphocyte aggregates forming nodules or follicles which are usually spherical or ovoid. Follicles may contain

Figure 1 The lymph node network. (Reproduced with permission from Roitt IM, Brostoff J and Male D (eds) (1998) *Immunology*, 5th edn. London: Mosby.)

tightly packed small lymphocytes and are termed 'primary follicles'. Alternatively, they may contain a central area consisting of larger lymphoid cells, macrophages and follicular dendritic cells. This central area is termed a 'germinal center' and the cuff of small lymphocytes that surround it forms the mantle zone. Nodules that develop a germinal center are termed 'secondary follicles'. Fully developed secondary follicles are composed of germinal center lymphocytes, mantle zone lymphocytes and macrophages/antigen-presenting (dendritic) cells. The germinal center is a site of active cell proliferation and cell death. A schematic model of the germinal center is shown in Figure 3. There are three major zones: a dark zone, a basal light zone and an apical light zone, and these are predominantly occupied by centroblasts, centrocytes and secondary blasts respectively. Primary B cell blasts which carry surface immunoglobulin receptors (sIg⁺) enter the follicle and leave as memory B cells or antibody-forming cells (AFCs). Antigen-presenting follicular dendritic

cells are mainly found in the two deeper zones, and cell death by apoptosis occurs mainly in the basal light zone where tingible body macrophages are also located. The lymphoid area between adjacent cortical follicles is called the 'interfollicular cortical tissue'.

The paracortex (or deep cortex) is a lymphoid area which is located immediately underneath the cortex, between the follicles and the medulla. Lymphocytes and lymphoblasts are densely packed in this area which displays a uniform lymphoid structure. Macrophages and antigen-presenting cells are interdispersed amongst the lymphocytes. Antigen-presenting cells are predominantly interdigitating cells similar to those found in the medulla of the thymic lobules. These cells, which belong to the monocyte/macrophage lineage, express membrane class II major histocompatibility complex (MHC) molecules at high density, have poor phagocytic ability and sparse lysosomes, but are very effective in presenting antigens to T cells. Other antigen-presenting cells are found in lymph vessels draining skin areas undergoing inflammation or antigenic stimulation. These are the 'veiled cells'. It appears that these veiled cells are Langerhans cells, which migrate from the epidermis where they are identifiable through the presence of Birbeck granules in their cytoplasm. Veiled cells reach the lymph node and seed into the paracortex where they lose their Birbeck granules and become interdigitating cells.

Another structural feature of the paracortex is the presence of high endothelial venules. These postcapillary venules are the sites where lymphocytes leave the circulation and enter the lymphoid tissue. The wall of these vessels is often infiltrated by small lymphocytes on their way from the blood into the parenchyma of the node. The lymph node medulla consists of cords of cells separated by lymphatic sinuses. Medullary cords are rich in plasma cells, macrophages and small lymphocytes.

Afferent lymphatic vessels enter the lymph node and empty into the large subcapsular sinus which lies directly beneath the capsule. Cortical sinuses run radially as extensions of the subcapsular sinus along the trabeculae, and continue between the medullary cords to converge into the terminal sinus, in the hilus region. One efferent lymphatic channel leaves the node emerging from the terminal sinus. Lymphatic sinuses are lined by endothelial cells and by macrophages termed sinus macrophages which become activated and increase in number during an inflammatory response.

Blood vessels enter the lymph node at the hilus. Arterioles reach the cortex through the trabeculae and break up into a rich capillary plexus. These ves-

Figure 2 The structure of a lymph node. (Reproduced with permission from Roitt IM, Brostoff J and Male D (eds) (1998) *Immunology*, 5th edn. London: Mosby.)

sels group into venules, tributaries of veins which run from the cortex into the medulla and then leave the node via the hilus.

Functional anatomy of the lymph node

A correlation between structure and function of the lymph node is shown in Figure 4. The lymph node cortex is generally regarded as a B-dependent area. Virgin B cells are found in the primary follicles of the cortex, whereas memory B cells account for the majority of the germinal center cells (centroblasts and centrocytes). Mature B lymphocytes expressing surface immunoglobulin M (IgM) and IgD are predominant in the mantle zone of secondary follicles. B and T cells are found together in the interfollicular cortical tissue and a few T cells with 'helper' phenotype (CD4⁺) are also detected in the germinal centers. Macrophages line the cortical lymphatic sinuses and are interdispersed in the follicular lymphoid tissue. Other macrophages are located within the secondary follicles, particularly between the mantle zone and the germinal center. Follicular dendritic cells are the antigen-presenting cells found in the germinal centers, whereas rare interdigitating cells are present in the interfollicular lymphoid tissue of the cortex.

Resting and activated T cells are the major components of the paracortex, which is therefore referred

to as a T-dependent zone. Antigens are presented to T lymphocytes by interdigitating cells. These are Langerhans cells which have migrated from the epidermis together with other antigen-presenting cells which reach the lymph node via the afferent lymphatic vessels. The paracortex is also an area of active cell traffic due to the presence of numerous high endothelial venules which are the major route for lymphocyte entry from the circulation into the lymph node.

The medulla is mainly a B-dependent zone, although T cells and macrophages are frequently detected in the medullary cords. Medullary B lymphocytes are antibody-producing effector cells, i.e. plasmablasts and mature plasma cells.

Antigens which have penetrated the surface defense barriers usually reach the lymph nodes via the afferent lymphatic vessels (Figure 4). Macrophages lining the lymphatic sinuses may transfer antigens to the T-independent and the T-dependent zones where cells equipped with specific antigen receptors can recognize them. Active recirculation of lymphocytes increases the chance of encounter between antigen and antigen-specific cells.

Stimulation of lymphocytes within the primary follicles by B-dependent antigens results in the development of secondary follicles with formation of germinal centers where antigens are sequestered and

memory B cells home. Antigen-activated B cells migrate to the medullary cords where they differentiate into antibody-producing plasma cells. Antibodies produced in the course of a humoral immune response leave the lymph node predominantly via the efferent lymphatic vessel. T-dependent antigens reach the lymph node via the afferent lymph usually carried by antigen-presenting cells (e.g. veiled cells) which home into the paracortical region and stimulate antigen-specific T cells. T cell proliferation and activation results in enlargement of this T-dependent zone. Activated T cells may also leave the lymph node via the efferent lymphatic vessel. Recently, adhesion molecules on both lymphoid cells and

Figure 4 (A) Lymph node structure. (B) Lymph node function.

endothelial cells have been shown to be of major importance in lymphocyte trafficking. These molecules play a role both in the random and nonrandom homing of lymphocytes.

LYMPHOCYTE FUNCTION-ASSOCIATED ANTIGEN 1 (LFA-1)

Eric Martz, Department of Microbiology and Program in Molecular and Cell Biology, University of Massachusetts, Amherst, MA, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Lymphocyte (leukocyte) function-associated antigen 1 (LFA-1) (CD11a/CD18) is a leukocyte integrin (β_2) adhesion molecule which plays a crucial role in the adhesions of most leukocytes to each other and to other cells, as well as in recognition of some microbes by phagocytes. LFA-1 typically forms adhesions by binding to ICAM-1, a ligand expressed by most tissues, or, on leukocytes or endothelium, also to ICAM-2 or ICAM-3. LFA-1's ability to engage ICAMs can be activated or inactivated within minutes by poorly understood configurational changes in LFA-1 ('inside-out signaling'). Activation is typically under the control of other receptors, for example the T cell antigen receptor in T cells. LFA-1-dependent cell adhesion is temperature, magnesium and cytoskeleton dependent. ICAMs bind to the inserted (I or A) domain of CD11a, where Mg^{2+} plays a critical role bound to a MIDAS motif. LFA-1 itself generates costimulatory signals ('outside-in signaling') that are probably important in leukocyte function. LFA-1 function is essential in most steps in the immune response, both in elicitation and in effector mechanisms, and is a target for pharmacological intervention.

Expression and nomenclature

LFA-1

LFA-1 is expressed on all leukocytes including B and T lymphocytes, monocytes, macrophages, neutrophils, basophils, and eosinophils, but is absent from nonhematopoietic tissues and human platelets. The α chain of LFA-1 is designated CD11a, and the β chain, CD18. However, since historically no other names have been used for LFA-1, both 'LFA-1' and 'CD11a/CD18' are unambiguous.

Leukocyte integrins

The leukocyte integrins are heterodimeric molecules, found on leukocytes, all sharing a common β chain, CD18. In addition to CD11a (LFA-1), they include CD11b (also called complement receptor type 3 or Mac-1, prominent on phagocytes and eosinophils), CD11c and CD11d. The leukocyte integrin α chain genes are linked on human chromosome 16; the gene for CD18 is on human chromosome 21. There are

several other families of integrins, each of which shares a different common β chain. All integrins are adhesion molecules, and all display temperature and divalent cation dependence for function. Although some nonleukocyte integrins require a highly conserved Arg-Gly-Asp (RGD) in their ligands (e.g. fibronectin), none of the ICAMs which bind to LFA-1 contain the RGD sequence.

Structure

CD11a

LFA-1 is an $\alpha_1\beta_1$ noncovalently linked heterodimer, CD11a/CD18 (Figure 1). Mature human CD11a, a glycoprotein of 180 kDa (126 kDa without glycosylation), consists of a 1063 amino acid extracellular domain including 12 N-linked glycosylation sites, a 29 amino acid transmembrane domain, and a 53 amino acid cytoplasmic domain. The extracellular portion contains seven repeats of roughly 50 amino acids each, five of which are in tandem. The extracellular portion also includes a single ~200 amino acid domain similar to domains found in a few nonleukocyte integrins, various receptors found also in invertebrates, some blood proteins, and in collagens and other matrix proteins. This domain is called the A domain because it was the first of five repeated domains, termed simply A through E, identified in von Willebrand factor. In the context of the leukocyte integrins, this same domain is often called the I domain (I for inserted/interactive).

Three of the seven repeated domains include EF-hand-like sequences which are putative divalent cation-binding sites. The I domain includes a different type of divalent cation-binding site called MIDAS (see below). The region containing the I insertion and the repeats has only a single N-linked glycosylation site and a single cysteine, consistent with ligand binding function (see below).

CD18

CD18, the LFA-1 β chain, is a 95 kDa glycoprotein. Mature LFA-1 β consists of a 677 amino acid extracellular domain containing six potential N-glycosylation sites, a 23 amino acid transmembrane domain, and a 46 amino acid cytoplasmic domain. The extra-

Figure 1 Structure of LFA-1 and its ligands ICAM-1, ICAM-2 and ICAM-3. Stippled regions participate in ligand binding; the MIDAS region of CD18 and other nonstippled regions may also participate. M^{2+} represents Ca^{2+} or Mg^{2+} . Numbers along the chains indicate the number of amino acids in each region. Transmembrane regions are black. C marks domains with similarity to immunoglobulin superfamily constant domains. The β chain of LFA-1 contains four tandem repeats of an eight-cysteine motif. Glycosylation is not shown.

cellular domain contains 56 cysteines, suggesting extensive intrachain disulfide linkage leading to a rigid structure, and may also contain a divalent cation-binding site of the MIDAS type (see below).

Polymorphisms

The mouse and human CD11a polymorphisms which have been noted to date appear to have no functional importance. Some CD18 polymorphisms, however, prevent expression with serious consequences (see LAD-1 below).

Ligands

Three ICAMs

The only ligands identified for LFA-1 (other than microbial ligands, see below) are the intercellular adhesion molecules ICAM-1 (CD54), ICAM-2 (CD102), and ICAM-3 (CD50), all of which bind in a temperature- and magnesium-dependent manner. Antibody blocking experiments are consistent with these being all of LFA-1's ligands. The three ICAMs are each glycosylated integral membrane proteins with a single transmembrane domain, and extracellular domains consisting of tandem head-to-tail immunoglobulin superfamily domains (Figure 1). All have rod-like configurations (ICAM-1 being bent), and in each case, one or two N-terminal domains

(farthest from the membrane) contains the LFA-1-binding site. ICAM-3, at least, can generate cytoplasmic signals, since certain antibodies to ICAM-3 activate LFA-1, VLA-4 and VLA-5.

ICAM-1 and ICAM-3 are heavily glycosylated (90–124 kDa, 55–59 kDa core proteins). ICAM-2 may be as well since it contains six predicted N-linked glycosylation sites. Different cell types glycosylate ICAMs differently. This affects binding of ICAM-1 to CD11b/CD18, but all forms of ICAM-3 appear to bind equally well to CD11a/CD18. CD11b/CD18 binds ICAM-1, but neither CD11b/CD18 nor CD11c/CD18 bind ICAM-3.

ICAM expression

ICAM-1 is expressed in most tissues at low levels, and expression is readily increased by inflammatory cytokines. In contrast, ICAM-2 is expressed primarily on endothelium and leukocytes (except neutrophils), and its expression generally is not responsive to cytokines. ICAM-3 is expressed on leukocytes and Langerhans cells, but not resting nor cytokine-induced endothelium, nor nonhematopoietic tissues. ICAM-3 predominates on thymocytes and resting lymphocytes, which are low in ICAM-1. When neutrophils are activated, they shed the majority of their ICAM-3 into the medium by proteolytic cleavage.

Microbial ligands

CD18 binds to certain bacteria (*Escherichia coli*) and fungi (*Histoplasma capsulatum*) in a temperature- and divalent cation-dependent manner. This is crucial for phagocytosis of the unopsonized forms of these microbes. Rhinovirus binds to ICAM-1 in a divalent cation-independent manner. *Plasmodium falciparum* also binds to ICAM-1, and both microbes depend on this binding for successful infection.

Function

Cell-cell adhesions

Nearly all leukocyte adhesions appear to depend on LFA-1. Some depend almost entirely, and some only slightly. Dependence is evaluated by the ability of LFA-1 α -specific antibody to inhibit the adhesion. In particular, the following adhesions are known to have a major LFA-1 component: T cell–antigen-presenting cell, T cell–B cell (in delivery of help), cytotoxic T lymphocyte (CTL)–target, natural killer cell (NK)–target, and macrophage–tumor cell. Following initial selectin-mediated adhesion and rolling under blood flow shear, neutrophils and other leukocytes employ LFA-1 to strengthen their adhesion to endothelium, and during subsequent transendothelial migration.

LFA-1-dependent adhesions of lymphocytes require magnesium and metabolic energy, and are inhibited by cytochalasins (which induce actin depolymerization). The adhesions are temperature dependent, forming within minutes at 20–37°C, and slowly at 15°C, with no detectable adhesion at 0°C. These characteristics are typical of all integrin-mediated adhesions. In contrast, the component of T lymphocyte adhesion which is mediated by CD2 binding to LFA-3 is independent of temperature and divalent cations.

Immune responses

LFA-1 is crucial to immune responses, consistent with its wide use in critical interactions of immunocytes. A rare congenital deficiency of the LFA-1 β chain, called leukocyte adhesion deficiency type 1 (LAD-1), is characterized, in its severe form, by profound immunodeficiency often fatal during the first 2 years of life. Patients have recurrent infections, granulocytosis, impaired pus formation, and delayed umbilical cord separation. *In vitro*, cells from LAD-1 patients have impaired adhesion of neutrophils and lymphocytes, resulting in deficient neutrophil, NK and CTL function, among others. A defect in the β chain in LAD-1 prevents surface expression of any of the three leukocyte integrins.

Antibodies to CD11a, CD18, or ICAM-1 have shown great promise as immunosuppressive and anti-inflammatory agents in animal models of reperfusion injury after ischemic events, autoimmunity, and transplantation. In contrast, soluble ICAM-1 has been relatively ineffective, perhaps because of low affinity. Although cyclic peptide antagonists of non-leukocyte integrins ('disintegrins') have shown promise in clinical trials, no such peptides are yet identified for CD11a/CD18. Clinical trials with antibodies have not completed phase III (efficacy in placebo-controlled, double-blind studies). Early indications with graft-versus-host (GVH) and cadaveric renal transplants are that antibody to CD11a may be effective as a prophylactic regime, but seems less effective as intervention for acute crises. Anti-ICAM-1 has shown promise in clinical trials with cadaveric renal transplants, liver transplants, and rheumatoid arthritis; trials with stroke and burn are underway. The most dramatic clinical results are for anti-CD11a therapy for bone marrow grafts in immunodeficient children, where the incidence of graft failure was reduced from 90% to 25% (51 cases). Because mouse antibodies, immunogenic in humans, have been used to date, this has prevented assessment of chronic therapeutic regimens; humanized antibodies are under development.

In vitro, LFA-1-specific antibody inhibits mixed leukocyte proliferative responses, T cell proliferation and interleukin 2 (IL-2) production to specific antigen, T cell proliferation to concanavalin A (but not to IL-2, nor B cell proliferation to lipopolysaccharide (LPS)), T cell-dependent antibody responses (but not T cell-independent antibody responses), and CTL and NK-mediated killing.

Molecular basis for function

Effects of antibodies

ICAM-1 and ICAM-3 bind to overlapping but different epitopes on LFA-1. Most antibodies to LFA-1 (either the α or β chains) or ICAM-1 inhibit adhesion function, some distinguishing between different ICAMs. Inhibitory antibodies often bind to CD11a at the I domain or the EF-hand-like repeats. Rare 'functionally neutral' antibodies neither inhibit nor activate adhesion (e.g. TS2/4), and these are thought to bind to nonfunctional epitopes. Some of these bind to the N-terminal region of CD11a (residues 1–57). A few antibodies activate function. Most of these bind to CD18, but rare examples bind to CD11a. Some activating antibodies have been shown to reduce the concentration of magnesium required for half-maximal function.

Divalent cations

LFA-1-dependent adhesion requires magnesium, in contrast to some other integrins and cadherins which are calcium dependent. Physiological $[Mg^{2+}]$, about 3 mM, is sufficient for optimal LFA-1 function with or without calcium. In the absence of magnesium, calcium supports no adhesion, and calcium reduces the efficacy of magnesium. (A synergistic effect of calcium observed under some circumstances could well result from an influx into the cytoplasm, rather than a direct effect on extracellular LFA-1). Manganese supports LFA-1 function with several times the potency of magnesium, and is useful for experimental maneuvers but is not believed to be bound to LFA-1 under normal conditions. The effects of divalent cations on function are complex and probably involve more than one of the five or more putative divalent cation-binding sites in CD11a/CD18.

The I domain and its MIDAS motif

The I domain of CD11a is believed to be the binding site, or a crucial part of the binding site, for ICAMs. A discontinuous magnesium-binding site has been identified in the I domain, termed the MIDAS motif (metal ion-dependent adhesion site). This motif is made up of AspXSerXSer (where X represents any amino acid) plus Thr and Asp in distant parts of the chain, arranged in proximity to the metal ion in the tertiary structure. In CD11a, magnesium is bound to Asp137GlySerMetSer plus Thr206 and Asp239 (Figure 2). CD18 probably also contains a functional MIDAS motif. Mutation of Asp134 or Ser136 in CD18 allowed expression with CD11a or CD11b, but produced loss of ligand binding in each case.

In both CD11a and CD11b, one of the six coordination sites of the magnesium ion is not coordinated by the I domain. This site is likely to bind a negatively charged residue on the ICAM ligand, such as Glu34 in ICAM-1 or Glu37 in ICAM-3, shown by mutagenesis to be critical for binding, and hence probably Glu40 in ICAM-2. It is not clear at present whether this proposed metal-to-ligand bond is essential for ligand binding. Alternatively, the metal may stabilize the necessary binding site, rather than being a critical part of the binding site itself.

Regulation of function

Rapid activation and inactivation

Efficient leukocyte function requires that leukocytes be selective about the cells to which they adhere. Adhesion responses must often be made within seconds to minutes. Early observations showed that mouse CTLs adhere to cognate (specific antigen-

bearing) target cells (forming 'conjugates') but showed little or no adhesion to noncognate targets. The time required for half-maximal conjugate formation was as short as 1 min. LFA-1 plays a crucial role in such conjugate formation, and is under the control of the T cell antigen receptor. More recently, selectins and the VLA-4 integrin have been shown to mediate leukocyte attachment to and rolling on endothelium under blood flow shear stress. LFA-1 does not engage ICAMs under shear stress, but when activated on an already attached, rolling leukocyte, LFA-1 can cause rolling to cease, immobilizing the leukocyte prior to its extravasation by migration through the endothelium (diapedesis).

Human CTL clones (unlike mouse CTLs produced *in vivo*), and B lymphocyte cell lines transformed by Epstein-Barr virus, show promiscuous adhesion which is LFA-1 dependent. This seems likely to result from constitutive LFA-1-activation signals produced by regulatory disturbances during long-term culture or viral gene expression.

The adhesion function of cell surface LFA-1 for ICAM-1 can be changed rapidly, without any change in the number of LFA-1 molecules on the cell surface. This activation or deactivation is normally under the control of other plasma membrane receptors (some of which may be integrins), and may also involve some positive or negative cytoplasmic feedback signals from LFA-1 itself. Antibodies or ligands for dozens of diverse plasma membrane receptors have been shown capable of activating LFA-1. For example, antibody to CD3 activates LFA-1 transiently on T lymphocytes, peaking at about 10 min. In common with many other receptor-controlled cellular events, physiologic activation of LFA-1 involves a complex interaction of tyrosine and serine/threonine kinases and phosphatases, and elevation of cytoplasmic calcium. Cyclic AMP inhibits activation of LFA-1 induced by certain receptors. The cytoplasmic domain of CD18 contains two AsnProX₂Phe sequences which are conserved in six of the eight integrin β chains. Evidence from β_1 and β_3 suggests that these may be important in regulation of function. Membrane-proximal portions of the cytoplasmic domains of both chains, including ValGly-PhePheLysArg in CD11a, appear to be important for heterodimer formation and regulation of function.

Experimental activation

In addition to physiologic activation by receptor cross-talk, LFA1 (and other integrin) function can be activated by several experimental maneuvers. Phorbol esters potently activate LFA-1 function, probably via their well-known activation of C-type protein kinases, since diacylglycerol transiently activates

LFA-1. The LFA-1 cytoplasmic domain serine most heavily phosphorylated in response to phorbol ester, Ser756 in CD18, was mutated without effect on regulation of function. For some cell types, certain kinase inhibitors (e.g. staurosporine) activate LFA-1. Recently it has been reported that the reducing agent dithiothreitol (DTT) induces activation of LFA-1. Ample magnesium (>1 mM) in the absence of calcium (EGTA), or manganese (0.1 mM) in the absence of calcium, activate LFA-1. As mentioned above, certain unusual antibodies to LFA-1 activate it. Some of these methods may activate LFA-1 to a higher quantitative or qualitative level than occurs physiologically.

Mechanism of activation

Activation via receptor ligation or phorbol ester is temperature dependent and requires metabolic

energy. This is called 'inside-out' activation. However, activation by the binding of magnesium or manganese, or by activating LFA-1-specific antibodies, is (by analogy with other integrins) effective on purified integrins, and hence occurs by direct interaction with the extracellular domains. There is evidence consistent with physiologic activation involving an increased affinity for magnesium, hence increasing occupancy of a critical metal-binding site.

The mechanism of activation of LFA-1 is not understood in detail, but must involve conformational changes. Rare antibodies recognize epitopes present only on an activated form of LFA-1, consistent with the expected configurational change. Results suggest that only a minority of the LFA-1 molecules on a cell may be active at one time. Activation of LFA-1 probably involves both a change in intrinsic affinity for ligand, and clustering of LFA-1 molecules on the cell surface, which increases functional affinity through multivalency. Some recent evidence indicates that clustering is calcium dependent, and may be prerequisite but not necessarily concurrent with the final activation event.

The low affinity of soluble ICAM-1 for LFA-1 has hampered studies of intrinsic affinity. One indirect

Figure 2 Structures of the ligand- and divalent cation-binding I domains of CD11a. (Stereo pairs for wall-eyed viewing made with the program RasMol.) (A) Backbone cartoon of the I domain of CD11a (atomic coordinate file 1LFA.PDB, from Qu A and Leahy DJ (1995) *Proceedings of the National Academy of Sciences of the USA* **92**: 10277). Mg^{2+} is shown as a black sphere. The five residues of the MIDAS motif which coordinate Mg^{2+} are shown as darkened stick representations. (Some of the coordinations are via water molecules, not shown. Mn^{2+} was the divalent cation in the crystal from which this structure was determined.) The darkened sections of the backbone indicate the positions of the strained hydrophobic ridge residues Met140 and Leu203LeuLeu, which is unique to CD11a and may be important in binding ICAMs. (B) Enlargement of the Mg^{2+} from (A), with the five MIDAS residues identified. (C) Spacefilling representation of the putative ligand-binding face of the I domain of CD11a. Mg^{2+} is black. Backbone and polar side-chains are gray, charged side-chains are white, and hydrophobic side-chains are dark gray. The inset identifies the four dark residues which make up the strained hydrophobic ridge. The letters S, T, E mark Ser245, Thr243 and Glu146, which along with Met140 are the major contributors to species-specific binding of ICAM-1. (From Huang C and Springer TA (1995) *Journal of Biological Chemistry* **270**: 19008–19016.) (D) Spacefilling representation of the putative ligand-binding face of the I domain of CD11b, colored as in (C). Note the absence of the hydrophobic ridge pattern seen in CD11a. Letters D and T mark residues that are crucial for iC3b binding but not for metal binding (Asp248, Thr252). (From McGuire SL and Bajt ML (1995) *Journal of Biological Chemistry* **270**: 25866–25871.) (Atomic coordinate file 1IDO.PDB kindly provided by Amin Arnout. estimate of K_d was approximately 10^{-4} M, and was consistent with 15–30% of the LFA-1 molecules being activated by phorbol ester, achieving a K_d of approximately 10^{-6} M. Integrins which have higher affinities for their ligands than does LFA-1 can be activated in solution (e.g. by manganese or activating antibodies) to bind to ligand columns, suggesting an increase in the intrinsic affinity of a univalent interaction. Recently it has been reported that ICAM-1 is normally dimeric on the cell membrane.

A recent comparison of two crystal forms of the CD11b I domain suggests structures for its active and inactive conformations. In the active conformation, Mg^{2+} is coordinated by uncharged residues (Ser, Thr, water), making it more electrophilic and likely to bind a negatively charged residue in the ligand. In the inactive conformation, Mg^{2+} is coordinated by a charged residue (Asp) making it less likely to bind an acidic group in the ligand. Ca^{2+} , were it to occupy the MIDAS site, is more likely to require coordination by the Asp, hence to stabilize the inactive configuration. The inactive conformation also buries two Phe residues and hides an acidic pocket which could be involved in ligand binding. These configurational changes are similar to those observed during function of G proteins, which are similar in structure to I domains.

It seems certain that the actin filament cytoskeletal system plays a role in LFA-1 function. Cytochalasins (which inhibit actin polymerization) have long been known to be potent antagonists of LFA-1-mediated leukocyte adhesions. Activation of LFA-1 may involve anchoring of LFA-1 to the actin filament system, or actin-dependent clustering of LFA-1 molecules into multivalent plaques. Filamin and α -actinin binding sites have been identified in the cytoplasmic domain of CD18. Evidence from chimeric receptors suggests that the CD18 cytoplasmic

domain sequence Thr758ThrThr, shown to be essential for cell adhesion, is involved subsequent to ligand binding in actin-dependent spreading.

LYMPHOCYTE FUNCTION-ASSOCIATED ANTIGEN 3 (LFA-3)

Steve Herrmann, Genetics Institute, Cambridge, Massachusetts, USA

Lymphocyte (leukocyte) function-associated antigen 3, also termed LFA-3 or CD58, is expressed as either a transmembrane or a lipid-linked cell surface protein. The transmembrane form consists of a 188 amino acid extracellular region, a 23 amino acid transmembrane hydrophobic region, and a 12 amino acid intracellular hydrophilic region ending in the C-

terminus. The lipid-linked form consists of the extracellular portion anchored to the membrane via a phosphatidylinositol membrane lipid. Treatment of cells with a phospholipase specific for phosphatidylinositol will solubilize the phospholipid-linked form of LFA-3. The LFA-3 on erythrocytes is anchored via the phospholipid linkage while other cells, such as

the Epstein-Barr virus transformed B cell line JY, express both transmembrane and lipid-linked LFA-3. The LFA-3 molecule is widely distributed and found on most hematopoietic cells, fibroblasts, epithelial cells, and endothelial cells. The expression of LFA-3 by antigen presenting cells (APCs), including macrophages, dendritic cells and B lymphocytes, implies a role in regulating the immune response.

Interaction with CD2

Initially, LFA-3 was defined by the ability of a monoclonal antibody (mAb) to block human cytolytic T lymphocyte (CTL)-mediated lysis by binding to the target cell surface. However, even before this discovery, a method widely used by immunologists to purify human T cells by forming rosettes with sheep red blood cells utilized the molecular interaction between LFA-3 and its ligand. The CTL-mediated lysis of targets as well as T cell rosetting was also inhibited by mAbs which bound to CD2 on the T lymphocytes. These antibody-blocking studies suggested that CD2 and LFA-3 were both involved with cell-cell adhesion.

Subsequent studies demonstrated that purified LFA-3 incorporated into the lipid bilayer of large lipid vesicles could bind to cells expressing CD2. Protein micelles, another form of multivalent LFA-3 prepared by detergent dialysis of purified phosphoinositol (PI)-linked LFA-3, bound to CD2-expressing cells with a K_d in the range of 0.5 nM. Bivalent LFA-3-Fc, prepared by splicing residues 1-184 of LFA-3 to the hinge and C_{H2} - C_{H3} region of human immunoglobulin G1 (IgG1), would also bind to cells expressing CD2 with a K_d in the range of 150 nM. Soluble monovalent LFA-3 prepared by expression of amino acid residues 1-180 in CHO cells demonstrated weak binding to CD2. In a recent study using surface plasmon resonance technology, the association of soluble LFA-3 to immobilized CD2 was found to occur quickly; however, the dissociation was also very rapid, $k_{off} \geq 4 \text{ s}^{-1}$, resulting in a low affinity, $K_d \approx 15 \text{ } \mu\text{M}$. Since all interactions would not reverse at the same instant, weak interaction between individual LFA-3/CD2 molecules would be stabilized if present as multivalent interactions. Provided the density was sufficient, the fast rate of association would ensure new interactions that would maintain adhesion. The experimental data with bivalent LFA-3, LFA-3 micelles and LFA-3-containing lipid membranes support this idea.

Using fluorescence photobleaching recovery of a planar phospholipid membrane containing purified fluorescently tagged phosphatidylinositol-linked LFA-3, the interaction between CD2 on the T lymphocyte

membrane and LFA-3 in a lipid planer membrane has been quantitated. This study reported the two-dimensional dissociation rate constant to be about 20 LFA-3 molecules μm^{-2} of membrane. (This measurement was based upon the density of LFA-3 in the contact area (bound) and the density outside the contact area (free) to calculate the number of molecules per unit area of membrane to give equilibrium binding.) Most APCs express LFA-3 at levels several fold above this density suggesting that laterally mobile LFA-3 should readily promote adhesive interactions with cells expressing CD2. However, the transmembrane form of LFA-3 has a much slower membrane mobility than PI-linked LFA-3 and would probably require a greater membrane density to achieve the same level of adhesion found for the lipid-linked LFA-3 in model membranes. This and a previous study indicated that the multivalent interaction between LFA-3 and CD2 in different membranes was favorable but dependent upon the membrane density and mobility of the receptor-ligand pair.

Human LFA-3 (CD58) and its receptor, CD2, are both encoded on chromosome 1 and consist structurally of two extracellular immunoglobulin-like domains. There is 21% homology between these two glycoproteins, suggesting that they arose from a single ancestral gene that encoded for a self-binding or homophilic type protein. Interestingly, a homolog of LFA-3 has not been found in mice and rats. However, a protein structurally similar to LFA-3, CD48, which is also encoded on chromosome 1 in humans, appears to be utilized in both rodent species comparably to LFA-3 in humans. In studies using surface plasmon resonance, binding between human soluble CD48 and CD2 was not found; however, binding between rat CD48 and CD2 was demonstrated and determined to have a K_d of about 80 μM . Although somewhat less than the interaction of LFA-3 with CD2, this level of binding in multivalent form should be sufficient to mediate adhesion in the rodent immune system.

The regions of LFA-3 required for binding to CD2 have been mapped by limited mutagenesis of the extracellular domain. Two regions containing charged amino acids in the first Ig-like domain were required. Specifically, amino acids 30, 34 and 84 of LFA-3 were shown to be essential for binding to CD2. Modeling by comparison with the structure of CD2 places these sites in two loop-out regions on one face of the LFA-3 molecule. From the position and complementarity of these charged groups, it appears that the LFA-3-CD2 interaction is mediated in part by interactions between amino acids with opposite charges.

Cell stimulatory signals

Based upon the structure of CD2 and LFA-3, the dimensions of each molecule would position the membrane of the LFA-3-bearing cell about 150 Å from the membrane of the cell expressing CD2. This distance would be optimal to encourage an interaction between the antigen specific receptor (TCR) on T lymphocytes and the peptide antigen presented by major histocompatibility complex (MHC)-encoded proteins on the surface of the APC. Numerous studies have supported this by showing that the interaction of LFA-3 with CD2 enhanced the responsiveness of T lymphocytes to antigen, presented by either class I or class II MHC. Under defined experimental conditions, lipid vesicles containing both LFA-3 and MHC-antigen triggered a several-fold greater response compared to liposomes containing MHC-antigen only. Similar studies indicated that anti-CD3 or lectin was able to trigger a greater T cell response in the presence of cells expressing LFA-3 or LFA-3 micelles. Thus, the LFA-3-CD2 interaction can deliver a costimulatory signal for both naive lymphocytes and previously activated or memory lymphocytes. This costimulation appears to involve a combination of adhesion properties, which promote antigen recognition, as well as delivering a direct costimulatory signal through CD2.

In addition to costimulation in the presence of antigen, it is also possible for CD2 to deliver a stimulatory signal in the absence of antigen. Certain pairs of anti-CD2 mAbs (e.g. T11₂ + T11₃) have been shown to activate T cells in the absence of an apparent antigen signal. It remains unclear whether this is due to an activation site on CD2 whose ligand has not been defined or results from antibody-mediated clustering of cell surface CD2. Recent studies suggest that LFA-3 alone can deliver an activation signal to T lymphocytes and this signal is transmitted through CD2. Proliferation and interferon γ (IFN γ) production by post-activated phytohemagglutinin (PHA)-stimulated T cells in response to interleukin 12 (IL-12) was shown to be dependent on the presence of macrophages expressing high levels of LFA-3. Although LFA-3 was also present on B cells and T cells in the culture, these cells could not support IL-12-driven proliferation and IFN γ production. The apparent reason for this was the (~10 $\times$) higher cell surface expression of LFA-3 on the macrophage surface. CHO cells expressing levels of LFA-3 similar to that on the macrophages would also support the IL-12-mediated responses, suggesting that a high surface density of LFA-3 was all that was required for T cell stimulation under these conditions. This type

of cytokine signaling would drive an IFN γ -dominant response commonly referred to as a T_H1-type immune response.

These data are consistent with a model where cell surface LFA-3 on monocytes or other APCs can mediate adhesion with T cells expressing CD2 and support antigen recognition, perhaps by providing a region for the MHC-peptide accumulation on the APC and TCR accumulation on the T cell. Once an activation signal is delivered by APCs, additional signaling through CD2 will directly drive T cell proliferation or expansion of the responder population. The requirement of a high surface density of LFA-3 on APCs implies that a polar clustering of CD2 is necessary and sufficient to deliver a stimulatory signal to previously activated lymphocytes. Reports indicating that IL-12 production by APCs is mediated by cross-linking of CD40, and the observation that CD40L on T cells was upregulated in response to endothelial cells expressing LFA-3, suggests that additional cellular components may contribute to this activation loop.

The interaction of CD2 with LFA-3 has also been reported to deliver a signal in the other direction, to the cell expressing LFA-3. In this study cross-linking LFA-3 on the monocyte surface induced the production and release of tumor necrosis factor α (TNF α) and IL-1 β . The lack of an extensive cytoplasmic domain on LFA-3 suggests that this signaling must be mediated through interactions with other cellular proteins.

Although the mechanism is far from clear, it has been shown that signals delivered through the TCR and accessory molecules in an imbalanced manner can lead to anergy or even T lymphocyte apoptosis. The human immunodeficiency virus (HIV) envelope protein, gp120, can also mediate anergy and apoptosis, presumably by binding to CD4 and seven-span chemokine receptors. Several studies have implicated the LFA-3-CD2 interaction in the reversal of these forms of anergy and apoptosis. These effects are apparently associated with signaling by CD2. Experiments show that the first domain of LFA-3 (or both extracellular domains) expressed as an Fc fusion protein will inhibit both primary and secondary T cell proliferation to antigen, lectin or anti-CD3 mAb, resulting in an anergic state. It is not clear if this is due to inappropriate signaling through CD2 or to the desensitization and/or blockade of CD2, rendering it unable to function in a normal manner. Consistent with these *in vitro* observations, *in vivo* studies demonstrated an increased survival of allografts in mice treated with anti CD2/anti-CD48, or in nonhuman primates treated with LFA-3-Fc.

Summary

LFA-3 (CD58) is a membrane protein found on nearly all human cells. The interaction between LFA-3 and CD2 is very weak in solution, but when these glycoproteins are present in different membranes, the multivalent action of the receptor/counter-receptor pair leads to effective cell-cell adhesion. In the presence of an antigen signal for T lymphocytes, this binding leads to a costimulatory signal and an enhanced response. Cells with a high density of LFA-3 can support proliferation and cytokine production by preactivated T lymphocytes in the absence of an antigen signal. The ability of LFA-3, through its interaction with CD2, to deliver signals that enhance T cell responses or modulate anergy/apoptosis indicate that regulation of this receptor-ligand pair may have therapeutic potential.

LYMPHOCYTE TRAFFICKING

Reinhard Pabst and Jürgen Westermann, Centre of Anatomy, Medical School of Hannover, Hannover, Germany

Richard M Binns, Babraham Institute, Babraham, Cambridge, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Lymphocyte traffic is essential for the interaction of the full antigen receptor repertoire on the lymphocyte surface with antigens wherever and whenever they enter the body. Lymphocytes migrate continuously from the blood into lymphoid and nonlymphoid organs and back to the blood via lymphatics and venules. On average lymphocytes stay in the blood-stream for only about 30 minutes on each passage. This means that the pool of lymphocytes circulating in the blood pool is exchanged about 48 times per day, and that in humans about 5×10^{11} lymphocytes leave the blood every day (Figure 1). This is in contrast to other leukocytes, for example granulocytes, which circulate for about 20 h in the blood, extravasate only once into the tissues and never return to the circulation again. Therefore, the regulation of the 0.25×10^{11} granulocytes leaving the blood each day into the tissues can only occur at the entry sites – endothelial cells of capillaries and venules. Lymphocyte migration, however, can be regulated during entry, transit and exit. There are indications that the migration patterns of natural killer (NK) cells and monocytes lie between these two extremes.

The detailed migration routes of lymphocytes, their kinetics and the regulation during entry, transit and exit of lymphoid and nonlymphoid organs are all included nowadays in the term lymphocyte trafficking. In the following, some of these aspects will be outlined in more detail and it will be stressed that these features may differ depending on which lymphocyte population is investigated.

Migratory routes of lymphocytes

In 1885 Walter Flemming argued that lymphocytes in lymphatics are not only newly formed cells but also lymphocytes on their way back to the blood. It took about 70 years until Gowans provided experimental evidence for lymphocyte traffic from the blood via lymph nodes into the thoracic duct of rats. Since then many studies have documented that similar mechanisms are at work in lymphocyte traffic in all mammals.

The vast majority of lymphocytes migrate from the blood into organs such as the lung, spleen, liver and bone marrow (Figure 1A). They enter the tissues and return into the blood using normal venules and sinusoids. Entry of lymphocytes into the spleen,

Figure 1 Each day about 5×10^{11} lymphocytes leave the blood to migrate into various organs and return into the blood. (A) Most of the blood lymphocytes enter organs such as the lung, spleen, liver and bone marrow via normal venules and sinusoids. The entry is protease-resistant and the lymphocytes have a short residence time in the organs. The vast majority return into the blood via normal venules. Only a few lymphocytes leave these organs via the afferent lymph. (B) In humans about 0.3×10^{11} lymphocytes migrate daily from the blood into organs such as the lymph nodes, tonsils and Peyer's patches. They use HEVs, the entry is protease-sensitive and the lymphocytes have a long residence time in the tissue. The lymphocytes return into the blood via the efferent lymph. (C) Only very few lymphocytes migrate under normal circumstances into organs such as the skin, synovia, muscle and brain. They enter these tissues via normal venules and their numbers are only related to blood flow. The lymphocytes return into the blood either via normal venules or via afferent and efferent lymph. However, during acute and chronic inflammation HEV-like structures may develop, leading to a large increase in lymphocyte influx, indicated by the thicker arrows.

which is best understood, seems to be via the marginal zone, and subsequently T and B lymphocytes use different routes through the splenic compartments. The majority leave via the splenic vein and not via lymphatics. On a quantitative basis several-fold more lymphocytes recirculate through the spleen and probably each of the other tissues than through all lymph nodes together. It is often overlooked that the bone marrow and the thymic medulla are included in the normal migratory route of lymphocytes. In addition, nonlymphoid organs, such as the lung and liver, contain large pools of temporarily sessile lymphocytes within the vascular bed, the so-called marginal pool (Figure 2). This is not the result of nonspecific trapping but a specific physiological phenomenon, at least for the lung.

Less than 10% of all lymphocytes in the blood migrate into organs such as the lymph nodes, tonsils and Peyer's patches (Figure 1B). They use specialized venules, the so-called high endothelial venules (HEV). The lymphocytes return into the blood via the efferent lymph (classic pathway of lymphocyte recirculation). The transit time of lymphocytes from the blood through lymph nodes into the thoracic duct is longer than that through organs not possessing HEVs.

Only very few lymphocytes migrate under normal circumstances into organs such as the skin, synovia, muscle and brain (Figure 1C). They enter these tissues via normal venules and return into the blood either via normal venules or via afferent and efferent lymph. However, during acute and chronic inflammation HEV-like structures may develop, leading to a large increase in lymphocyte influx. The signals involved in the switch from a normal endothelial cell to a specific exit site for lymphocytes are not known.

There appears to be a further area of complexity. In species like pigs, sheep and calves there are two types of Peyer's patches in the small intestine, which differ in lymphocyte entry from the blood by a factor of up to 10. This heterogeneity has also been found for the different tonsils and lymph nodes and also in the appearance of lymphocyte migration in ontogeny. In addition, it is well-known that within organs, B and T lymphocytes travel differently through the various organ compartments.

The migration described so far is probably indicative of the routes of naive lymphocytes because in most experiments unseparated lymphocyte populations were used which usually contain few activated or memory lymphocytes.

Migratory routes of lymphoblasts

After presentation of the respective antigen and appropriate costimulation, naive lymphocytes become lymphoblasts and start proliferation. The traffic of proliferating large lymphoid cells shows a different pattern. Most typically, after injection immunoglobulin A (IgA) lymphoblasts from thoracic duct, Peyer's patches or mesenteric lymph nodes are preferentially found in the lamina propria of the gut. In addition, injected lymphoblasts from the gut-associated lymphoid tissue, but not from peripheral lymph nodes, are found preferentially in organs with mucous layers, such as the bronchial tract, lacrimal, salivary and mammary glands. It has to be stressed, however, that it is a preferential and not an exclusive location.

Figure 2 Different steps in lymphocyte migration. The mechanisms involved in lymphocyte adhesion to endothelium are known in considerable detail, although lasting only in the range from seconds to minutes. In contrast, the regulation of lymphocyte migration during transit and exit are not well understood, although these phases last for hours, leaving time for intensive interaction with the extracellular matrix (ecm), fibrocytes (fc), macrophages (mac), dendritic cells (dc) and various chemokines (ch) and cytokines.

Migratory routes of memory lymphocytes

It had been proposed that naive lymphocytes exclusively enter lymph nodes via HEVs (Figure 1B), and memory T lymphocytes enter tissues such as the skin and then finally reach the lymph node via afferent lymphatics (Figure 1C). However, the evidence was indirect. More recent *in vivo* studies using different techniques showed that memory lymphocytes also migrate through HEVs and are found in the efferent lymph. However, it is always problematic to deduce functions from phenotype analysis (as it is necessary to identify naive and memory lymphocytes in migration studies), and therefore the terms naive and memory have to be used with caution. Thus, only when the traffic of marked lymphocyte subsets is followed *in vivo* is it possible to define the traffic routes used by various lymphocyte subsets.

Techniques to study lymphocyte migration

As in other processes *in vivo*, effective physiological study of the routes followed by migrating lymphocytes calls for minimal and innocuous intervention. First, use of lymphocytes from the blood or lymphatics, typically the thoracic duct, has the advantage that those lymphocytes are already in transit, in contrast to those extracted from lymphoid organs, which are a mixture of sessile and mobile lymphocytes. The cells must be labeled to be traced and this can be done by using isotopes, such as ^{51}Cr , [^3H]-cytidine or [^3H]-lysine to label all lymphocytes, or [^3H]-thymidine and [^{125}I]-uridine to label mainly lymphoblasts since these isotopes are only incorporated in proliferating lymphocytes. Fluorescent dyes (e.g. fluorescein isothiocyanate, FITC) have proven valuable labels for tracing lymphocytes *in vivo* and *in vitro*. Used in combination with identification of surface markers, resting and activated lymphocyte subsets can be identified among migrating cells, both in suspension and also in tissue sections. In species in which congenic strains exist (e.g. mouse, rat, pig), lymphocytes can be transferred without any *in vitro* labeling procedure and the route of injected cells through lymphoid organs followed by identifying the cells with monoclonal antibodies. Thus, using adequate techniques the detailed routes of migration of lymphocyte subsets through lymphoid and non-lymphoid organs and their subcompartments are being identified.

Alternatively, *in vitro* techniques have proved very useful for the molecular study of lymphocyte adhesion to blood vessel endothelia. For example,

lymphocyte binding to HEVs of lymphoid tissues can be analyzed on cryostat sections. HEV cells from lymph nodes in rodents can also be cultured *in vitro*, and the interaction between lymphocytes and these endothelial cells can be studied in more detail. Cultured human umbilical venous endothelial cells (HUVEC) are often used to study the mechanisms involved in lymphocyte binding. However, it has to be considered that this endothelium might differ in major aspects from the endothelia in lymphoid organs. A major advantage was the establishment of *in vivo* videomicroscopy, allowing the analysis of migrating lymphocytes under physiological shear forces.

In all the different techniques used to study lymphocyte traffic, the extent to which the methodology may have altered the physiological processes has to be considered and compared critically.

Regulation of lymphocyte migration

Migration can be regulated during entry into, transit through and exit from lymphoid and non-lymphoid organs (see Figure 2). The vast majority of studies were and still are concerned with regulation of lymphocyte traffic during entry.

Entry

When lymphocytes enter a lymph node, Peyer's patches or tonsils from the blood, only certain specific sites in the vascular bed are used for migration into the parenchyma. These preferential sites for binding and emigration of lymphocytes are the post-capillary venules in the paracortex, which in most species have a high endothelium. Initially it was assumed that migration into peripheral lymph nodes is mediated by a single molecule on the lymphocytes, called a 'homing receptor', and the corresponding molecule on the HEV, the 'addressin'. Another pair of molecules was thought to be responsible for migration into Peyer's patches. However, it is now clear that a steadily increasing number of receptor pairs exists for the different lymphoid tissues. There is a partly overlapping sequence of interaction of adhesion molecules on lymphocytes and endothelial cells. Some adhesion molecules are expressed constitutively and others are inducible by chemokines and cytokines. Lymphocytes are found in the peripheral blood (circulating pool), and also near to or in intermittent contact with the vessel wall (marginal pool; Figure 2, Table 1). The emigration through the vessel wall can be divided into several steps: 1) Lymphocytes make contact with the endothelium and, under appropriate conditions, start to roll on the endothelium, also called tethering. 2) By factors coming

Table 1 Factors influencing lymphocyte entry

Steps during entry	Properties	Implications
Marginal pool (reversible)	Cellular composition	Determines cell type available for immigration
Adhesion to endothelium (reversible)	Shear force	Physical properties important for the availability of adhesion molecules
	Cell charge	
	Length of adhesion molecules in relation to other surface molecules e.g. CD45: 300 nm; L-selectin: 30 nm	
	Position of adhesion molecules	Mainly involved in the early phase of adhesion
	at the tip of microvilli e.g. L-selectin and $\alpha_4\beta_7$ -integrin	Mainly involved in the late phase of adhesion
	at the cell base e.g. LFA-1 and CD44	
	Change of adhesion molecule conformation e.g. LFA-1 within seconds	Facilitates or inhibits adhesion molecule function
	Shedding of adhesion molecules e.g. L-selectin within seconds	Facilitates or inhibits adhesion molecule function
	Release of chemokines	Alters functional state of adhesion molecules
	Rolling on already adherent neutrophils, lymphocytes, platelets	Makes adhesion molecules available which are normally not present on the endothelium
Transmigration (irreversible)	Type of endothelium, e.g. flat or high	Selective entry of leukocyte subsets, e.g. normally only lymphocytes but no granulocytes migrate through high endothelium
	Site of transmigration, e.g. inter- or intracellular	
	Induction of degrading enzymes, e.g. gelatinase for basal lamina	

from the endothelial cells or from beneath the basal membrane, lymphocytes become activated, also called triggering, resulting in strong adhesion to the endothelial cell. 3) Finally the lymphocytes start the transmigration, also termed diapedesis. The transmigration is associated with a dramatic change in the morphology of the lymphocytes, e.g. they lose the microvilli on their surface and the cytoplasm forms a uropod. These phases are regulated by different pairs of adhesion molecules, and factors possibly influencing this process are listed in Table 1. A further interesting aspect is the time schedule: lymphocyte activation takes place in a few seconds, strong adhesion in a few minutes but the transmigration lasts several minutes (Figure 2).

The role of adhesion molecules has been elucidated by studies *in vitro* and *in vivo* using inhibitory antibodies against adhesion molecules on both lymphocytes and endothelial cells. More recently, experiments in mice deficient in certain adhesion molecules have extended our knowledge about the role of individual molecules in different lymphoid organs. L-Selectin knockout mice, for example, not only show blocking of lymphocyte entry into peripheral lymph nodes (as expected) but also a severe reduction in entry into Peyer's patches. Thus, it has become obvious that one should not speculate on a functional role of an adhesion molecule only based on its pres-

ence on a cell type. As an example, it has been documented that the adhesion molecule MAdCAM-1, initially thought to be specific for migration into Peyer's patches, is also expressed on cells of the marginal zone of the spleen, but blocking this molecule had no effect on lymphocyte migration into the spleen. So far, no specific molecules have been identified regulating lymphocyte traffic to organs without HEV, such as the spleen, bone marrow, lung and liver.

Recent data showed that some adhesion molecules are concentrated at the tip of the microvilli, whereas others are located at the cell base, indicating different roles in the interaction with the endothelium (Table 1). In addition, adhesion molecules are shed from the cell surface and found as soluble molecules in the serum. The regulatory and potential therapeutic role of these soluble molecules has to be studied in more detail.

Transit and exit

After a lymphocyte has left the blood and migrated via an intercellular route between endothelial cells, the transit through the lymphoid organ starts (Figure 2). Lymphocytes will interact with the extracellular matrix, e.g. with fibronectin, laminin, collagens, and also interstitial cells such as fibrocytes, macrophages and dendritic cells. This transit lasts for hours and enables intercellular contacts and effects of cytokines

and chemokines in a paracrine fashion. Very little is known about regulation of the transit through the organs. Finally, most lymphocytes will leave the lymphoid organ again and exit into venules or lymphatics. No regulatory factors have been characterized for this step so far. However, there are indications that this step is carefully regulated. For example, sheep lymphocytes efficiently used the HEVs within pig lymph nodes to exit into the blood, a route normally not taken by sheep lymphocytes. In addition, pig lymphocytes migrated from lymph nodes of fetal lambs into lymphatics, a route not taken by pig lymphocytes but normal for sheep lymphocytes. This suggests that the mechanisms regulating lymphocyte migration are well conserved, at least between these two species which diverged from a common ancestor about 50 million years ago.

Conclusions

The continuous traffic of lymphocytes through lymphoid organs is an essential component of the immune system: there are only few immunocompetent lymphocytes for a specific antigen and this traffic vastly increases their probability of meeting the antigen in the appropriate microenvironment around accessory cells and other lymphocyte subsets which are important for the initiation of effective immune responses. Lymphocyte traffic in general is not dependent on antigens. Sheep fetuses have normal lymphocyte recirculation through lymphoid tissues and into the thoracic duct, although they are secluded from external antigens by their particularly impervious placenta.

The entry into lymphoid organs through HEVs is regulated by a series of sequentially involved receptor–ligand interactions by several adhesion molecules. Certain models, e.g. the preferential route of ‘memory’ and ‘naive’ lymphocytes, have had to be revised recently. Much less is known about factors that may regulate transit within the lymphoid organs and the exit from the organ. Cytokines may play important roles in all these steps of transit through an organ. Little is known about the regulation of lymphocyte traffic to lymphoid organs without HEVs and to nonlymphoid organs such as the lung and liver.

LYMPHOCYTE TRANSFORMATION TEST

Charles H Kirkpatrick, Division of Allergy and Clinical Immunology, Department of Medicine, University of Colorado Health Sciences Center, Denver, Colorado, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The lymphocyte transformation test is based on the observations that, in response to activation with mitogens, antigens, superantigens and antibodies to components of cell membranes, lymphocytes synthesize proteins such as immunoglobulins, cytokines and growth factors, enter the cell cycle, synthesize DNA and replicate, and undergo metabolic and morphologic changes. T lymphocytes are activated by mitogens such as phytohemagglutinin and concanavalin A, superantigens, anti-CD3 and antigens that are presented by antigen-presenting cells. B Lymphocytes are activated by anti-immunoglobulins, bacterial lipopolysaccharides and staphylococcal protein A.

The lymphocyte transformation test has become one of the most widely used *in vitro* tests for evaluation of lymphocyte functions in clinical immunology. The general procedures used in this test are also used to study the biochemical events that accompany lymphocyte activation, effector functions of activated lymphocytes and to produce clones of specific antigen-responsive lymphocytes.

Historical background

Perhaps the first use of mitogens in lymphocyte biology was described by Peter Nowell in 1960 when he reported that phytohemagglutinin, a protein from the red kidney bean, *Phaseolus vulgaris*, would stimulate DNA synthesis and cell proliferation in cultures of blood lymphocytes. The first applications to immunologic studies were described by Bach and Hirschhorn and associates in the early 1960s, and soon the test was applied to studies of lymphocytes from patients with immunodeficiency syndromes, malignancies and other disorders of the immune system. It is now one of the most widely used tests for *in vitro* studies of lymphocyte functions in clinical immunology. The clinical studies have shown that there is usually a close concordance between antigen-induced lymphocyte proliferation *in vitro* and expression of delayed-type hypersensitivity to the same antigen.

Procedures

Lymphocyte transformation test using human peripheral blood lymphocytes

1. Venous blood is aseptically collected into heparinized (20 units ml⁻¹) syringes or tubes.
2. The heparinized blood is diluted with an equal volume of Hank's balanced salt solution (HBSS) or phosphate-buffered saline (pH 7.4) (PBS) and then layered over a mixture of Ficoll and Hypaque that has a specific gravity of 1.077. Sterile preparations of Ficoll-Hypaque are commercially available. The tubes are centrifuged at 500 g at room temperature for 30 minutes. The mononuclear cells are concentrated between the uppermost plasma layer and the middle layer of Hypaque-Ficoll. They are recovered by aspiration with a sterile pipet. Erythrocytes and granulocytes sediment to the bottom of the tube.
3. The mononuclear cells must be washed at least twice with tissue culture media or HBSS to remove the Hypaque-Ficoll. At this point an aliquot of the cell suspension is removed for a cell count and differential. Normal subjects usually yield about 1 million lymphocytes per milliliter of whole blood and the final product contains 75–85% lymphocytes and 10–20% monocytes. The distribution of T lymphocytes, T lymphocyte subsets and B lymphocytes in the final product is proportional to the ratios of these cells in the original specimen.
4. The cells are suspended in tissue culture medium (RPMI 1640 is commonly used) that has been supplemented with fresh glutamine (200 mM), penicillin (100 units ml⁻¹), streptomycin (100 µg ml⁻¹) and heat-inactivated serum (5%). Depending on the goal of the experiment, the serum may come from a fetal bovine calf, the original blood donor or a pool of group AB human sera. A cell density of 10⁶ cells ml⁻¹ is common. There is a good deal of individuality in the fine points of human lymphocyte transformation tests, with some workers preferring HEPES-buffered media and gentamicin or amphotericin B as additional antibiotics.
5. The cells are distributed into culture trays or culture tubes in concentrations of 200 000 cells per well in round-bottom 96-well trays or 10⁶ cells

ml⁻¹ in culture tubes. The stimulating agent is added in a volume of 10–50 µl and the culture vessels are incubated at 37°C in an atmosphere of 5% CO₂ and 95% air. It is best to do dose-response studies in which several doses of the stimulating agent are used. For example, phytohemagglutinin (PHA-M) can be used in concentrations of 0.1, 1.0 and 10 µg ml⁻¹. With lymphocytes from normal donors, half-maximal responses are obtained with doses of 0.3–0.5 µg ml⁻¹ of PHA-M. Concanavalin A is used in doses of 0.5, 5.0 and 10 µg ml⁻¹ and pokeweed mitogen is used in doses of 1.0, 10 and 30 µg ml⁻¹.

6. Most clinical studies are intended to examine the responses of a patient's lymphocytes to antigens from infectious agents such as herpes simplex, mycobacteria or *Candida albicans*, or toxins such as tetanus toxoid or staphylococcal enterotoxins. Many of these preparations are not standardized for potency and dose-response experiments are necessary. For example, our laboratory uses ultraviolet-irradiated herpes simplex virus in doses of 10⁶, 10⁷ and 10⁸ plaque-forming units (PFU) ml⁻¹; tuberculin PPD in concentrations of 1.0, 10 and 30 µg ml⁻¹; *Candida albicans* in doses of 1, 10 and 100 µg ml⁻¹; and tetanus toxoid in doses of 0.01, 0.1 and 1.0 limit flocculation units (LFU) ml⁻¹. Each dose is studied in triplicate and a set of unstimulated cells serves as the control for spontaneous activity.
7. The duration of culture varies with the stimulant used. For mitogens, peak responses with human cells occur on day 3; for antigens peak responses occur on day 5 or day 6; and when allogeneic cells are used as the stimulant in mixed leukocyte reactions, peak responses occur on day 6 or day 7. In these last experiments the stimulating cells are 'blocked' by irradiation or incubation with mitomycin C (50 µg ml⁻¹ for 20–30 minutes at 37°C), after which the mitomycin is removed by washing.

Lymphocyte transformation test using murine lymphocytes

In many studies it is desirable to study responses by a subpopulation of cells from a lymphoid organ, and it is necessary to selectively remove the cells of interest from complex mixtures. It is also desirable to remove erythrocytes from suspensions of spleen cells.

1. Lymphoid tissues from donor mice are aseptically collected and placed in cold tissue culture medium. The organs are minced with sterile scissors,

and single cell suspensions of lymphoid cells are obtained by gently pressing the tissue through 60 mesh stainless steel screens or 200 µm mesh nylon screens with the plunger from a 3 ml hypodermic syringe. The cells are suspended in a test tube in tissue culture medium and clumps of 'debris' are allowed to settle by standing the tube at an angle of 60° in an ice bath. After 10–15 minutes the cells are collected by decantation.

2. For spleen cell suspensions it is desirable to remove erythrocytes. The cells are suspended in 2–3 ml of fetal calf serum and 5 volumes of EDTA-ammonium chloride solution is added. After incubation on ice for 20 minutes the lymphoid cells are collected by centrifugation at 700 g for 10 minutes and washed twice with tissue culture medium.
3. At this stage the cell mixtures contain T lymphocytes, B lymphocytes and accessory cells (and other cells if thymus was used). They may be cultured at this stage or processed further to collect specific cells of interest. This can be done by 'positive selection', in which cells are preferentially removed from the mixture, or 'negative selection', in which the undesired cells are removed, leaving the cells of interest (Table 1). In general, positive selection is more specific, while negative selection serves to enrich the fraction of cells of a particular subtype.

Table 1 Selection of specific cell populations

Positive Selection

1. Panning by incubation of cells on plastic surfaces that are coated with monoclonal antibodies against immunoglobulin for B lymphocytes, anti-Thy-1 for T lymphocytes, or anti-CD4 or anti-CD8 for T lymphocyte subsets
2. Collection of selected cell populations on antibody-coated magnetic beads
3. Collection of antibody-coated cells by fluorescence-activated cell sorting (FACS)
4. Collection of dendritic cells and macrophages on plastic surfaces

Negative Selection

1. Depletion of adherent cells. Cell mixtures are incubated with nylon wool or Sephadex G-10 in small columns. B Lymphocytes and accessory cells adhere to the columns but T lymphocytes do not. They are collected by elution
2. Depletion by cytotoxicity. Cell suspensions are incubated with monoclonal antibodies against the undesired cell population. The sensitized cells are lysed by addition of complement. Anti-Thy-1 antisera remove T lymphocytes and anti-immunoglobulin or anti-MHC class II antisera remove B cells and accessory cells

Culturing murine lymphocytes

In general, murine lymphoid cells require enriched media with larger concentrations of glucose (Iscove's media or Dulbecco's MEM with high glucose), 5–10% fetal bovine serum, L-glutamine and 2-mercaptoethanol (5×10^{-5} M). Accessory cells such as irradiated or mitomycin-treated syngeneic spleen cells provide nutrients for optimal cell proliferation and are required as antigen-presenting cells in studies of antigen-induced proliferation. A mouse spleen yields $1\text{--}2 \times 10^8$ cells with approximately 33% of these cells being T lymphocytes.

The cells are suspended in the complete medium at a concentration of 10^6 cells ml^{-1} and distributed into wells of tissue culture trays (flat bottom) or culture tubes. The wells contain 200 000 cells and tubes contain $1\text{--}2 \times 10^6$ cells. If the cells have been separated from accessory cells it is necessary to add 'feeder cells' in the form of irradiated or mitomycin-treated syngeneic spleen cells with approximately 10^6 feeder cells per well or 5×10^6 cells per tube.

At this stage the stimulants may be added to the cultures, and the cells are ready to be incubated at 37°C in CO_2 -air.

Mixed leukocyte reactions

Responses to alloantigens are measured in cultures containing responder cells and allogeneic stimulator cells that have been treated with irradiation or mitomycin C. The treated cells cannot contribute to the proliferation or transformation response, but serve as sources of alloantigens. B cells, dendritic cells and macrophages serve this function.

Proliferation responses are usually maximal at day 6 or 7. This test is widely used for pairing donors with recipients for bone marrow transplantation.

Lymphocyte transformation tests with whole blood

With infants and small children it is often difficult to remove enough blood for detailed studies of lymphocyte responses to antigens and mitogens; however, an assay using whole blood can be used for screening such subjects. First, one should do a leukocyte count and differential to determine the number of lymphocytes. Then a sample of blood from a heel stick or a small volume of heparinized venous blood is diluted with 9 volumes of tissue culture media, as described above, and the cell suspension is distributed into culture trays or tubes. Often, there are so few cells that only a single dose of each antigen or mitogen can be evaluated; the dose that produces optimal responses in normal subjects should be used.

The culture conditions and harvesting are the same as described above, except that just prior to har-

vesting the cultures, the erythrocytes must be lysed with distilled water, EDTA-ammonium chloride solution, or a commercial lysing solution such as Zap-Isoton® (Coulter). If this is not done, the color from the hemoglobin will quench the counts per minute (c.p.m.) in the liquid scintillation spectrometer.

Quantitation of lymphocyte transformation responses

Since the introduction of the lymphocyte transformation test, the most widely used readout has been measurement of DNA synthesis with radioactive tracers such as ^3H - or ^{14}C -thymidine. The isotope is usually added during the final 4–16 hours of culture. The cells are then collected on filter paper disks, washed to remove unincorporated radioactivity and the incorporated radioactivity is measured with a liquid scintillation spectrometer.

Data from such experiments may be presented in a number of ways including net c.p.m. in which mean c.p.m. from unstimulated cultures are subtracted from mean c.p.m. of stimulated cultures, or as stimulation ratios (stimulation index) in which the mean c.p.m. in stimulated cultures is divided by the mean c.p.m. in unstimulated cultures. It has been argued that the mean c.p.m. should be logarithmically transformed to consider the exponential nature of cell division.

It is recommended that publications present the raw data to readers.

Nonisotopic assays for cell proliferation

The problem of disposing of radioactive waste has led to development of nonradioactive assays for DNA synthesis in lymphocyte cultures. 5-Bromo-2'-deoxyuridine (BrdU) is incorporated into the newly synthesized DNA and incorporation of BrdU is enhanced by addition of the thymidylate kinase inhibitor, 5-fluor-2'-deoxyuridine. The incorporated BrdU is detected with an antibody to BrdU and a peroxidase-conjugated second antibody in a standard ELISA assay. The reagents for this assay are available as commercial kits.

Alternative assays for transformation responses

An obvious shortcoming in the thymidine incorporation assay is that it only measures events during the later hours of the experiment. With the growing interest in the biology of lymphocyte growth and activation, new assays have been developed that measure events that occur soon after exposure of the cells to ionophores, mitogens and antigens. Other assays quantitate functional responses by activated cells such as secretion of immunoglobulins by B lymphocytes and cytokines by T lymphocytes.

- Changes in cellular ionized calcium (Ca^{2+}). Cells are loaded with a fluorescent dye such as Indo-1-AM and the cells are studied in a flow cytometer. Following addition of the stimulus the change in fluorescence profiles are monitored. Changes in calcium concentration in as few as 1% of the cells can be detected and may occur within 1–2 minutes after addition of the stimulus.
- Cell cycle analysis. Activated cells enter the cell cycle and synthesize DNA, which can be monitored by treating the cells with propidium iodide, an agent that reacts with double-stranded DNA. Changes in DNA synthesis can be detected in less than 24 hours if adequate numbers of cells are responding. The sensitivity of this assay greatly exceeds the traditional thymidine incorporation assay.
- Expression of cell membranes and receptors. Shortly after activation, B lymphocytes, macrophages and T lymphocytes express greater numbers of major histocompatibility complex (MHC) molecules and T lymphocytes express interleukin 2 (IL-2) receptors. These changes can be demonstrated within 24 hours after activation by staining cells with the appropriate monoclonal antibodies and performing FACS analysis.
- Cytokine production. Activated T lymphocytes secrete factors such as interferon γ and interleukins (IL-2, IL-4). Significant concentrations of cytokines can be detected by ELISA as early as 12 hours after activation.
- Immunoglobulin (Ig) synthesis and secretion. B lymphocytes secrete IgM, IgA, IgG and IgE in response to activation with anti-immunoglobulin, lipopolysaccharide, pokeweed mitogen or other activators. It usually requires 4–5 days to produce amounts of immunoglobulin that can be detected by radioimmunoassay or ELISA.

Clinical applications

The test is most commonly used to investigate suspected immunodeficiency in patients with unusual susceptibility to certain infectious diseases. Patients with severe immune deficiencies such as severe combined immunodeficiency (SCID) have little or no lymphocyte transformation responses to mitogens or antigens, even when they have normal numbers of lymphocytes in their blood. In other disorders, such as chronic mucocutaneous candidiasis, responses to mitogens may be normal, but the patients' lymphocytes do not respond to antigens, especially antigens from *Candida albicans*.

The test is also useful for identifying serum factors that inhibit normal lymphocyte transformation

responses. In these cases (such as patients with recurrent vaginal candidiasis, chronic mycobacterial infections or Hodgkin's disease) the proliferation responses are normal in normal serum but subnormal in autologous serum.

Recently, superantigens such as bacterial enterotoxins have been implicated in certain autoimmune diseases and toxic shock syndrome. These agents activate large numbers of T lymphocytes to proliferate and secrete cytokines.

The lymphocyte transformation test has also been useful for studying mechanisms of lymphocyte activation and in identifying critical cell interactions (e.g. CD40–CD40 ligand) and defects in signal transduction.

The small lymphocyte has a nucleus of mainly condensed chromatin and a scant cytoplasm that contains relatively few organelles. While we now know that this unremarkable morphology is associated with a wide phenotypic and functional heterogeneity, in the 1950s there were very diverse views about these cells, being regarded by some as multipotential stem cells and by others as long-lived cells that were terminally differentiated. In less than 50 years this situation has radically changed: not only is the central role of the lymphocyte in immunity established, but our understanding of these cells continues to grow at a truly impressive rate.

By the mid-1960s studies by Medawar and by Gowans had established that graft rejection, graft-versus-host reactions and antibody formation were all mediated by the progeny of small lymphocytes that underwent blast transformation when stimulated by antigen. Further, the demonstration by Gowans that lymphocytes recirculate from blood to lymph by passage through specialized endothelial cells in lymph nodes resolved the paradox that large numbers of these cells enter the lymph each day but are not a short-lived population.

While these studies established the role of the lymphocyte in the adaptive immune response they did not explain how a single cell type could have such a diverse range of functions. However, by 1967 the work by Miller on the effects on the immune system of neonatal thymectomy and of Mitchell and Miller on the role of thymus-derived lymphocytes in the generation of antibody responses demonstrated that small lymphocytes, despite their uniform morphology, consisted of subsets of cells with different functional attributes and different tissues of origin. This functional specialization provided an explanation of the experiments by Mitchison on the hapten-carrier effect in which he showed that the induction of hapten-specific antibody synthesis by lymphocytes of bone marrow origin (B cells) required the 'helper' activity of thymus-derived lymphocytes (T cells). These experiments, at least in retrospect, suggested what is now an established fact, specifically that B cells and T cells require different types of antigenic stimulation in order to respond.

The applications of classical serology and the study of B cells in experimental systems soon made two significant contributions to the study of lympho-

cyte heterogeneity: B cells were shown to express surface immunoglobulin which further experiments showed had the same antigen specificity as that secreted by the plasma cell progeny of these B cells. In contrast, T lymphocytes did not express surface immunoglobulin but a lineage-specific marker was discovered in the mouse whose thymocytes and peripheral T cells were found to express the Thy 1 antigen. The clonal nature of B cell surface immunoglobulin provided an explanation of the demonstration by Nossal (1960) that no plasma cell was found to produce antibody of more than one specificity and confirmed Burnet's clonal selection theory of antigen recognition.

The next major development came from studies of cytotoxic T lymphocytes which help to eliminate viruses by killing virus-infected cells. In 1974, Zinkernagel and Doherty found that these cytotoxic T cells killed their targets only if they shared the same haplotype of the major histocompatibility complex (MHC). This phenomenon of MHC restriction led to a series of experiments to determine whether T cells expressed two receptors, one for self-MHC and the other for antigen or whether T cells recognized 'altered self'. The altered self hypothesis was supported by the finding, in 1986, by Guillet and coworkers, that short peptides bound to MHC molecules were recognized by antigen-specific T cells. However a full explanation of MHC restriction had to await the X-ray crystallographic studies by Bjorkman and her colleagues which showed in 1987 that antigen-specific receptors on a T cell recognize a complex determinant made up of an antigenic peptide locked into the antigen-binding site of an MHC molecule. Those T cells that recognize MHC class I-peptide complexes express the CD8 cell surface antigen and their target cells present peptides derived from cytoplasmic proteins. In contrast, T lymphocytes that recognize peptide in association with class II express CD4 and in this case the antigenic peptides originate from extracellular proteins that are taken up by the class II positive antigen-presenting cells (APCs). The MHC restriction exhibited by cytotoxic lymphocytes with respect to MHC class I antigens is now known to be also a characteristic of CD4⁺ T cells interacting with peptides bound to MHC class II. Thus T cells that provide B cell help become activated by MHC class II-peptide complexes on APCs

and subsequently the activated T cells help when they recognize the same complexes on B cells.

In both APCs and B cells antigen is processed internally into peptides which are loaded into MHC class II molecules and transported to the cell surface. However, whereas the uptake of antigen by APCs is nonspecific, the uptake by B cells is antigen-specific and is mediated by the immunoglobulin receptors on the B cell surface. This dual recognition of antigen, conformational determinants of proteins by B cells and peptide determinants by T cells, has probably evolved to ensure an extra degree of specificity control in the antibody response. This view is supported by the observation that self-tolerance at the T cell level is more extensive than it is for B cells.

The further study of the immune system was immeasurably facilitated by two technological advances. In the 1950s immunologists had been quick to make use of the fact that the ability of the immune system to generate antigen-specific antibodies provided them with a valuable way of studying the distribution of antigens within tissues and the source of immunoglobulin-producing cells. However the full exploitation of antibodies as immunological tools became possible only when, in 1975, Köhler and Milstein developed monoclonal antibodies (mAbs). The great value of these reagents was not only that they were antigen-specific but also, as Williams showed in 1977, they could be raised against unknown antigens that might constitute only a minor part of a complex mixture of immunogens. With mAbs it was soon shown that small lymphocytes were phenotypically much more diverse than the applications of classical serology had suggested and the CD4/CD8 dichotomy, to which reference has already been made, is but one example of this. The identification by mAbs of different subsets of lymphocytes made possible detailed functional studies of the roles of these different cell types and helped to establish lineage relationships between them. Further, they could be used to specifically interfere with intermolecular interactions and thus give indications of the functions of these molecules. Antibodies identified by such studies have become potential therapeutic agents.

The second major advance was the development of gene sequencing by Sanger in 1975 and of recombinant DNA technology by Sambrook and many others. An early consequence of the application of this methodology was the characterization of antibody genes by Tonegawa and others, and later of the T cell receptor genes by Davis, Mak and others. The nature of the diversity among B cell receptors at the protein level had been largely established by classical amino acid sequencing by Milstein and others but

a detailed understanding of the genetic basis of this diversity awaited the ability to sequence the genes themselves. The results of DNA sequencing showed that both B cells and T cells generate their repertoires of receptors by random rearrangements of DNA segments obtained from a large pool of genetic elements. (The process can be considered loosely akin to the generation of a dictionary of words by the use of only 26 letters.) Further diversity is generated during the process of gene rearrangement, by introducing or deleting a few base pairs at the junctions between the genetically encoded elements. Finally, among B cells, but not T cells, the receptor genes may undergo somatic mutation during an immune response.

The applications of gene sequencing and recombinant DNA technology, which enables genes to be expressed at the protein level and mutants and chimeric molecules to be generated at will, has had an impact on cellular as well as molecular immunology. It has proved possible to develop transgenic mice that express an experimentally introduced gene and to produce mutant mice in which a selected gene has been eliminated by homologous recombination. By the application of these new techniques at least a partial understanding in molecular terms has been obtained of lymphocyte homing, of lymphocyte effector functions and of self/nonself discrimination. It is known that lymphocytes interact with each other and with other cell types, such as antigen-presenting cells, endothelial cells and virus-infected target cells both through cognate cell/cell interactions and via the synthesis and binding to surface receptors of soluble mediators termed cytokines. Many of the molecules involved have been cloned at the DNA level and expressed as recombinant proteins. These reagents provide material both for basic biochemical studies and for the derivation of specific mAbs that block their effector functions. The *in vivo* and *in vitro* use of these reagents, commonly cytokines and antibodies to them, has already enabled immunologists to selectively promote cell-mediated or humoral responses to antigens and have provided insights into the way that the immune response is physiologically regulated. A major advance has been the recognition that different subsets of CD4⁺ T cells exist, which produce distinct combinations of cytokines that mediate either humoral or cell-mediated immunological functions. Curiously it has recently been found that the experimental use of immunological mediators has been anticipated by pathogenic viruses which have captured genes from their mammalian hosts and use the products of these genes to their own advantage. It is highly probable that some lymphocyte genes will be first discovered in viruses.

In the review of lymphocytes, in the first edition of this encyclopedia, Gowans pointed out that our understanding of the function of these cells has developed only over about the last 40 years. There has been a most impressive expansion in knowledge in that interval but despite this progress there is some way to go before we can give a comprehensive explanation, in molecular and genetic terms of the beneficial effects of vaccination, a prophylactic procedure that was introduced by Jenner 200 years ago.

LYMPHOKINE-ACTIVATED KILLER (LAK) CELLS

Ronald B Herberman, University of Pittsburgh Cancer Institute, Departments of Medicine and Pathology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, USA

In response to exogenous activation stimuli, e.g. interleukin 2 (IL-2), some T lymphocytes as well as natural killer (NK) cells increase in size, become more granular and acquire the ability to bind to and kill a wide spectrum of tumor cells, virally infected cells and even some normal tissue cells. Such IL-2-activated effector cells have been referred to operationally as lymphokine-activated killer (LAK) cells. In studies using blood from normal human donors, the phenomena of NK and LAK activities were shown to be closely related; however, in some cancer patients or for cells from other organs, LAK cells may consist of both NK and T cells at various stages of activation and in various proportions.

Operationally, LAK cells are defined as lymphocytes that mediate non-major histocompatibility complex (MHC)-restricted cytotoxicity against a broad array of targets following *in vivo* or *in vitro*

activation with IL-2 alone or in combination with other cytokines. The LAK phenomenon was originally described by Grimm and colleagues in 1982, and since then it has become clear that LAK cells do not represent a novel lymphocyte type, as initially suggested. More recent studies have demonstrated that LAK cells are derived from either NK or T lymphocytes, although in the blood of normal human donors, NK cells are the predominant precursor cells. B cells or monocytes do not give rise to LAK cells. Recently, several other surface markers with different molecular weights and functional properties, such as DM1, VGO1 and LAK1, have been described to identify human LAK cell precursors. Among T cells, a small subset of CD3⁺ CD56⁺ lymphocytes (generally less than 1% of total T cells), which mediate non-MHC-restricted cytotoxicity, seems to be the primary source of LAK cell precursor

sors. On long-term culture with IL-2 or in the presence of CD3-specific antibodies, the contribution of this T lymphocyte subset to LAK activity appears to be substantial. In LAK cells the large granular lymphocyte (LGL) morphology (Figure 1) is characterized by a reniform nucleus and abundant cytoplasm rich in azurophilic granules, which contain cytolytic and some enzymes possibly involved in the cytolytic process mediated by LAK cells. A lysosomotropic amine, 1-leucine-methylester, is effective in inhibiting generation of LAK cells by removing granular lymphocyte precursors. Like NK cells, LAK cells are a source of multiple cytokines and release appreciable amounts of some cytokines, such as tumor necrosis factor α (TNF α) and interferon γ (IFN γ). On the basis of phenotype, origin and functional characteristics, NK and LAK cells represent cytotoxic effectors at different stages of activation: the former in the poised state, ready to accept an activation signal when it is delivered, the latter in the highly active 'killer' state after delivery and processing. When human peripheral blood mononuclear cells (PBMNCs) are incubated *in vitro* with IL-2, a proportion of these cells acquire a property of adherence to glass or plastic. These plastic-adherent cells have a phenotype of NK cells, i.e. are CD3⁺ CD56⁺ CD16⁺ LGLs, and they have been named A-NK cells, for activated, adherent-NK cells. This property of adherence to plastic has been used to isolate and culture highly enriched A-NK cell preparations from human PBMNCs. Vujanovic and colleagues have shown that A-NK cells are more cytotoxic against solid tumor cell masses than nonadherent LAK cells, have a greater ability to migrate into tumor spher-

Figure 1 Photomicrograph of natural killer (NK) cells, with morphology of large granular lymphocytes.

oids, and their precursors in blood can be isolated with a monoclonal antibody to an epitope on N-CAM.

To measure LAK activity, ^{51}Cr -labeled NK-resistant tumor cells, e.g. the human lymphoblastoid cell line Daudi, are used as targets. Effector cells may be fresh PBMNCs prepared by Ficoll-Hypaque centrifugation of human blood, body fluids, bone marrow or disaggregated lymphoid tissues. *In vitro*, IL-2-activated effectors may be generated (usually after culture for 3–4 days) and then assayed for NK or LAK activity. The cytotoxicity assays must be performed at multiple (at least four) effector (E) to target (T) ratios, e.g. E:T from 50:1 to 5:1, in order to analyze the dose-response relationship between the percentage of specific lysis and the number of effector cells present. The assay is technically simple and reliable when performed in a clinical laboratory setting.

A 4 hour ^{51}Cr -release assay involves incubation of a constant number of labeled target cells with graded numbers of effector cells in triplicate wells of a microtiter plate. Killing is quantitated by measuring the amount of ^{51}Cr released into the supernatant. The results of the assay can be expressed as a percentage of specific lysis or, more conveniently, as lytic units (LUs), defined as the number of effector cells required to kill a predetermined number of target cells. The number of effector cells in an LU depends on their potency or lytic ability, with smaller numbers of cells indicating more potent effectors. LUs are calculated on the basis of lytic curves, established by plotting the percentage of specific lysis for each E:T ratio and then transforming the resulting curve into LUs. Various approaches have been developed for transformation of cytotoxicity data into LUs. These systems are available as computer programs.

On a routine basis in a clinical laboratory, LAK cell assays can be performed reliably but only if stringent quality control measures are established to assure reproducibility and minimize daily variability of these assays. We have recently described a program for controlling the performance of the NK assay in a clinical laboratory, and have implemented similar requirements for the LAK assay. Measurements of LAK cells are strongly influenced by the quality of cells used in the assay. Therefore, storage of the effector cells, their cryopreservation, the presence of human serum and even the temperature of cell storage may influence to a considerable degree the cytolytic activity of effector cells. For these reasons, we prefer to perform LAK cell generation on fresh rather than cryopreserved cell suspensions, in fetal calf serum rather than human serum, and on cells collected within 24 hours of the performance of

the assay. The use of cryopreserved cells for LAK cell generation is not recommended because of variable and often considerable losses in the ability to respond to activators *in vitro*, which are observed with cells of many individuals.

Human NK cells can be induced to adhere to the plastic surface of a culture flask after 24 hours of incubation of peripheral blood lymphocytes (PBLs) with recombinant IL-2 (rIL-2). In response to exogenous IL-2, some NK cells in PBLs, presumably those that express the p75 β chain of the IL-2 receptor, adhere to the plastic before T lymphocytes do. In this way, activated NK cells can be captured on plastic and separated from T lymphocytes, whose activation and expression of surface adherence molecules require a longer period of time. Studies by Melder and coworkers have shown that cellular adhesion molecules are involved in the attachment of NK cells to plastic because this adherence can be reduced markedly by monoclonal antibodies to the CD11 and CD18 adhesion molecules. Incubation of A-NK cells in the presence of IL-2 and conditioned medium results in their proliferation, which may continue for 2–3 weeks in culture, yielding large numbers of highly purified NK cells (generally 80–99% purity) expressing high levels of antitumor cytotoxicity. Although nylon wool-passed PBLs are generally used for A-NK cell generation, human splenocytes and tonsils as well as liver-infiltrating lymphocytes have also been used to generate A-NK cells with comparable levels of purity and antitumor cytotoxicity as those of A-NK cells obtained from PBLs. Overall, the generation of A-NK cells from NK cells in response to exogenous IL-2 has several characteristics: induction of adherence to plastic; increased antitumor cytotoxicity against NK-resistant target cells; and proliferation in the continued presence of IL-2. Because human A-NK cells can be generated in substantial numbers, e.g. 2×10^9 A-NK cells from leukapheresed normal donors, they represent an excellent source of enriched NK cells for study of their characteristics. These cells have recently been used to investigate the process of activation of NK cells, the expression of the CD18/CD11 family of adherence molecules on their surfaces, the role of Fc γ RIII in cytotoxicity mediated by A-NK cells, *in vitro* production of cytokines by these cells, and their movement on plastic as well as *in vivo* in the microvasculature of tumors and normal tissues.

Human A-NK cells have been generated from the blood of patients with various malignancies, including ovarian, hepatocellular, colon, and renal cell carcinomas, metastatic melanoma, and glioblastoma, as well as in patients with acute lymphocytic or myelo-

genous leukemia. In many cancer patients, proliferative and cytotoxic properties of A-NK cells are equivalent to those seen with A-NK cells generated from normal human PBLs. However, in patients with bulky disease or those previously treated with chemotherapy or radiotherapy, the ability to generate A-NK cells appears to be impaired. Also in certain types of cancers, the phenotype of expanding adherent-LAK cells may be different from that of A-NK cells obtained from normal individuals. For example, in glioblastoma, particularly in patients maintained on relatively high doses of steroids, we found that adherent-LAK cells had a phenotype associated with non-MHC-restricted T cells, i.e. CD3⁺CD56⁺. Nevertheless, these glioblastoma patients' adherent-LAK cell cultures had levels of antitumor cytotoxicity that were markedly higher than those obtained with unseparated PBLs cultured in the presence of IL-2. In most patients with cancer, however, and in contrast to IL-2 cultured PBLs (which are mixtures of IL-2 activated NK cells and T cells), A-NK cells represent homogeneous populations of activated NK cells.

Approaches to immunotherapy with LAK or A-NK cells

Adoptive transfers of LAK cells and IL-2 to tumor-bearing animals were effective in inducing the regression of established lung, liver and subcutaneous metastases of immunogenic and nonimmunogenic sarcomas or adenocarcinomas. To achieve therapeutic effects with LAK cells plus IL-2, it was necessary to administer sufficient numbers of LAK cells and high enough concentrations of IL-2 and to reduce tumor burden by previous surgery or by including chemotherapy. Therapy with LAK cells of IL-2 administered as single agents had little or no antimetastatic effects in animals bearing non-immunogenic tumors. On the other hand, high doses of IL-2 alone could induce appreciable tumor reduction in animals bearing immunogenic tumors. Basically, the experience with LAK cells plus IL-2 in animal models indicated that this form of therapy could be effective against a metastatic tumor if the tumor burden were first reduced by surgery or chemotherapy. Complete elimination of existing micrometastases and long-term survival could only be achieved in animals receiving all three treatment modalities – surgery, chemotherapy and immunotherapy.

On the basis of results obtained in animal models treated with LAK cells plus IL-2 and of well-documented *in vitro* induction of LAK activity in PBLs from patients with cancer, phase I clinical trials were

performed to determine the toxicity and antitumor efficacy of this form of immunotherapy in patients with advanced malignancies. The results from these early trials, some performed with IL-2 alone and others with a combination of LAK cells and IL-2, have not been as encouraging as originally expected. More than 70% of patients with advanced malignancies treated with immunotherapy did not respond, and some patients demonstrated severe toxicities that were subsequently linked to the high doses of IL-2 administered. On the other hand, 25–30% of patients with metastatic melanoma and renal cell carcinoma unresponsive to conventional therapy responded to immunotherapy with LAK cells plus IL-2. As more experience with adoptive immunotherapy was acquired, it became clear that improvements in this form of therapy are necessary and may indeed result in better overall response rates. The advantages and disadvantages of continuous versus bolus administration of IL-2 have been debated. Lowering the concentration of IL-2 administered to patients with cancer in order to eliminate the vascular leak syndrome has been considered. Attempts were made to prolong the half-life of IL-2 *in vivo* by using IL-2 complexed with polyethylene glycol (PEG-IL-2) or by manipulating infusion schedules. Rosenberg and colleagues recently reported the results of a randomized comparison of treatment with high dose IL-2 alone versus LAK cells plus IL-2, and found that administration of LAK cells plus IL-2 has additional clinical therapeutic efficacy above that achieved with IL-2 alone. LAK cells may not represent an optimal population of cells for therapy. The LAK cells are heterogeneous populations of IL-2-activated autologous mononuclear cells, and their *in vivo* distribution and therapeutic efficacy can be variable, depending on their cellular composition and *in vitro* activation achieved.

Once methods for generating large numbers of A-NK cells were developed, preclinical studies were performed to assess the antimetastatic activity of these cells. In several different syngeneic tumor models, the number of lung and liver metastases was found to be substantially reduced after treatment with moderate doses of A-NK cells plus IL-2. *In vivo* support of the A-NK cells with PEG-IL-2 appeared to provide particularly beneficial results. In a human metastatic tumor model in nude mice, purified human A-NK cells plus IL-2 were shown to have very potent and rapid antimetastatic therapeutic effects. Based on such promising preclinical therapeutic results, clinical trials with autologous A-NK cells and moderately high doses of IL-2 have been initiated. These treatments have been well tolerated and some therapeutic efficacy has been seen.

To understand the basis for *in vivo* antitumor effects and to increase therapeutic efficacy, detailed studies have been performed to evaluate the *in vivo* distribution and function of adoptively transferred A-NK cells. By use of fluorescent-labeled A-NK cells, it has been possible to demonstrate the selective accumulation of the transferred effector cells at sites of tumor metastases (Figure 2). Efforts are now being directed towards maintaining or enhancing the antitumor functions of such tumor-infiltrating A-NK cells in order to maximize their therapeutic efficacy.

Figure 2 Localization of fluorescent-labeled murine A-NK cells, 18 hours after adoptive transfer intravenously to a mouse bearing metastases of B16 melanoma. (A) Distribution of fluorescent A-NK cells in lung; (B) stained adjacent section of lung, showing several micrometastases.

LYMPHOMA

George T Stevenson, Tenovus Research Laboratory, Southampton University Hospitals, Southampton, UK

Lymphomas are neoplasms (tumors) arising from lymphoid tissue. They display the basic characteristics of neoplastic growth (purposeless, progressive, parasitic), and are distinguished further by being commonly multicentric, due to early spread, even in their most benign forms. Spreading reflects the normal migratory behavior of the cells of origin; in con-

trast, the spread (metastasis) of an epithelial cancer is a criterion of malignancy.

The vast majority of human lymphomas of recognized lineage arise from T or B lymphoid cells, and are usually confined to a restricted range of maturation. Only an occasional tumor is seen to arise from natural killer (NK) cells, mononuclear phago-

cytes (monocytes and macrophages), and the various specialized antigen-presenting cells such as dendritic cells. Lymphoma presents usually in a major lymphoid organ – bone marrow, thymus, lymph node, spleen or mucosal tissue – but as normal lymphoid cells are virtually ubiquitous throughout the body it is not surprising that their tumors sometimes appear first in other organs such as brain.

The diversity of lymphomas, coupled with arcane nomenclatures, is on first acquaintance quite discouraging. However, they have an academic importance far greater than their incidence (about 5% of human cancer) might warrant. The ease with which their constituent cells can be isolated and studied in the test tube, coupled with our current understanding of the markers and functions of normal lymphoid cells, means that we have a greater knowledge of these tumors than of any other. Some, such as Burkitt's lymphoma, exhibit well-characterized karyotypic abnormalities with associated oncogene activation, and so acquired a major role in unravelling the molecular basis of malignancy. A T cell leukemia/lymphoma was the first – and remains the only – human tumor to be associated with an RNA retrovirus. The immunoglobulin (Ig) products of secreting B lymphomas, known collectively as myeloma proteins, were of great importance in the unravelling of Ig structure and genetics. Now the rearrangements of genes for Ig and the T cell antigen receptor (TCR), with the resulting idiotypic epitopes in their protein products, provide excellent criteria for clonality and for divergence of the original neoplastic clone. It is also of some interest that an animal lymphoma, Marek's disease of fowl, was the first tumor for which an effective vaccine (directed against the oncogenic chicken herpes virus) was developed.

Nomenclature and classifications

Modern use of immunologic markers often detects neoplastic lymphoid cells in the blood of patients presenting with a mass of solid lymphoma. If such cells are present in numbers sufficient to give an abnormally high lymphocyte count, the case can be regarded as one of leukemia. Conversely, a patient presenting with a frankly leukemic picture might be troubled later in the disease by solid accumulations of neoplastic cells. Clearly there is no sharp dividing line between solid lymphomas and lymphoid leukemias, as has been recognized in the recent Revised European American Lymphoma (REAL) classification. However, in most current texts, and in this entry, the two forms are treated separately in deference to current clinical practice.

Another problem of nomenclature arises with neoplasms of Ig-secreting B lymphoid cells, of which the most important representatives in humans are multiple myeloma and macroglobulinemia. These have some features sufficiently distinctive to lead to their being considered apart from lymphomas in most texts. In this entry the term lymphoma will be used to embrace all neoplasms of lymphoid cells, including the leukemias and Ig-secreting tumors.

To classifying lymphomas there is no end. The varying roles of viruses, the often multiple genomic lesions, and the interactions with normal tissues combine to present tumors of bewildering variety, with apparently unique features associated with each patient. Nevertheless those common features which can be discerned have led to insights into pathogenesis, and often reflect significant differences in prognosis and responses to therapy, so that the efforts of lymphoma taxonomists have been well justified. Each person approaching the subject must decide upon the depth of classification which their interests dictate. The basic classification of the commoner human lymphomas set out in Table 1 provides the major headings in this entry. Much further along the spectrum of complexity are the 50 or so types and subtypes of lymphoma listed in the well-researched and eminently expandable REAL classification. Unfortunately a vast amount of clinical data are locked into the Working Formulation, a classification of non-Hodgkin lymphomas (NHL) in widespread use since 1982 which omits references to cell lineages and has proved poorly adaptable to recent advances.

Lymphoid leukemias

Acute lymphoblastic leukemia (ALL)

This group represents the common leukemias of childhood. The commonest variant is pre-B ALL. Here the cells lack surface B markers, but rearranged Ig genes, sometimes accompanied by cytoplasmic μ chains, identify their B lineage. Other variants include B, T and null cell ALL, the last having no known lineage-defining features. All varieties exhibit a cellular morphology and markers typical of immature lymphoid cells. A well-known marker of imma-

Table 1 A basic classification of human lymphoma

<i>Leukemia</i>	<i>Solid lymphoma</i>

Chronic lymphocytic	Non-Hodgkin lymphoma
	Myeloma and macroglobulinemia

turity is the nuclear enzyme terminal deoxynucleotidyl transferase (TdT), whose normal role is to help diversify the antigen-receptor site in both T and B cells. ALL of childhood is one of the more successful arenas for modern chemotherapy: 5-year survivals are now at 60–70%, but achieved at the cost of considerable toxicity.

Chronic lymphocytic leukemia (CLL)

CLL in its common B cell form is the commonest of all human leukemias, with an incidence rising steeply with advancing age. The course of the disease is usually – although by no means always – fairly indolent, and it is probably true to say that B cell CLL found incidentally on medical examination after the age of 70 is of little actuarial consequence. The neoplastic cells, or the vast majority of them, resemble mature small lymphocytes with scanty cytoplasm. Their surfaces display B cell markers, including sparse surface Ig of uniform idiotype. They also often display CD5, which among normal cells is present on T cells and a small subset of B cells. Whether this means that the leukemia arises from the small B cell subset, or simply reflects circumstances which might induce any B cell to display the marker, is not apparent. The cell numbers in the blood can raise the lymphocyte count up to 200-fold. Cellular infiltrates enlarge and architecturally distort lymph nodes and spleen, and eventually pack out the marrow. Commonly death comes from marrow failure, from infection facilitated by immune deficiency, or from some unrelated age-associated problem.

Several uncommon variants of B cell CLL are recognized. The prolymphocytic variant displays larger cells with prominent nucleoli and abundant surface Ig. There is a tendency to infiltrate the spleen rather than lymph nodes, and a relatively malignant course. The cells of hairy cell leukemia display B cell markers, but have prominent surface villi and a capacity for phagocytosis – features which have not yet been identified among any normal B cell populations. This rare leukemia is also of interest because it will melt away (but not disappear entirely) in the face of interferon therapy.

In what may be called lymphoma spillovers, one sometimes encounters CLL-like blood pictures developing in the course of neoplasms which exist predominantly as solid lymphomas.

In the Western world T cell CLL usually presents with cells of 'large granular' morphology – medium lymphocytes with cytoplasmic azurophil granules. The appearance of such cells in the blood is often given the alternative designation T lymphocytosis, a term deliberately noncommittal as to whether the condition is neoplastic. There is, in fact, considerable

confusion at present regarding the significance of a blood picture of large granular lymphocytosis, which possibly can reflect at least three different conditions: CD8 cell CLL, NK cell CLL, and lymphocytic hyperplasia in response to chronic infection or other antigenic stimulus. Thus sometimes the lymphocytic cells display the surface molecule CD8 and a clonal rearrangement of the T cell receptor (TCR) genes, indicative of T cell neoplasm. Sometimes surface CD16 and other NK markers are present. Sometimes the picture is rendered more difficult by the presence of cells of mixed phenotype.

In southern Japan, the Caribbean basin and sub-Saharan Africa there occurs a relatively malignant adult T cell leukemia/lymphoma associated with the retrovirus HTLV-I (human T cell leukemia virus type I). In some areas this might represent the commonest form of leukemia. The viral infection is endemic in the tumor areas. The virus can spread from mother to child (mainly via milk), by blood transfusion, and probably at a low rate by sexual activity. Infection may be present for more than 30 years before the tumor appears, and the lifetime risk for carriers of the virus is probably not more than 1%. The cells are larger than in common CLL, are usually of CD4 phenotype, and display a relatively high density of receptors for the cytokine interleukin 2 (IL-2). Often there are skin infiltrations, lytic bone lesions and a marked hypercalcemia.

The Sézary leukemia is a well-known, although rare, neoplasm of CD4 lymphocytes which diffusely infiltrate the skin. The cells have characteristic deeply grooved 'cerebriform' nuclei. The infiltrated skin becomes red and can exfoliate. (Mycosis fungoides is a related lymphoma of CD4 cells, with skin infiltration which initially is patchy and indolent; the leukemic component is absent.) T cell prolymphocytic leukemia presents a clinical picture resembling that of the B cell type, but is rarer. The cells are usually of CD4 phenotype.

Hodgkin's disease

This tumor or group of tumors accounts for about a third of solid lymphomas in Western societies. It is an enigma in that although more successfully treated than other lymphomas (by chemotherapy and precisely controlled radiotherapy) its nature, i.e. the lineage of the neoplastic cell, remains a mystery. This cell (the Hodgkin cell, called a Reed–Sternberg cell when in bi- or multinucleate form) accounts in the vast majority of instances for only a tiny proportion (<3%) of the cells making up the tumor masses. It appears to be lymphoid in nature and frequently displays activation markers. However there has been no

consistent occurrence of T or B markers, nor of rearrangements of genes for Ig and the T cell receptor. Generally the predominant histological feature is a complex and variable inflammatory infiltrate comprising lymphocytes, macrophages, eosinophils, neutrophils and fibrous tissue. Such an appearance suggests a high local release of cytokines.

An interesting clinical feature is that the tumor is often seen to spread from a single original site. In this regard it differs from the non-Hodgkin lymphomas which are usually multifocal at the time of diagnosis. This difference means that the management of Hodgkin's disease depends more heavily upon an initial clinical 'staging', i.e. assessment of spread. The histological picture in Hodgkin's disease is also an important predictor of the clinical course. The commonly used Rye classification recognizes four variants called, in order of worsening prognosis, lymphocyte-predominant, nodular sclerosing (the most common type), mixed cellularity, and lymphocyte-depleted. Some evidence has recently been presented that the relatively uncommon lymphocyte-predominant type may in reality be a B cell lymphoma in most instances, and would be better considered apart from Hodgkin's disease.

Some epidemiological and genomic data suggest that the Epstein-Barr virus (EBV) has a contributory etiological role in many cases of Hodgkin's disease, particularly the mixed cellularity variety. In the AIDS-associated form of the disease the presence of EBV in the neoplastic cells is evident in virtually all cases.

Non-Hodgkin lymphoma (NHL)

This complex group of tumors have been seen to arise from all the known lymphoid lineages (B, T, NK, mononuclear phagocytic, dendritic). The lineage of origin in a given case can usually be identified without difficulty by a modern laboratory. However such information is rarely prominent in the clinical notes, first because it is not particularly discriminatory – more than 80% of NHL in Western societies arises from the B lineage – and secondly because clinicians, encouraged by classifications such as the Working Formulation, have long correlated prognosis and management with the 'grade' of tumor (low, intermediate or high) suggested by conventional histology. However closer studies of tumor behavior, and the advent of immunotherapy, are encouraging greater interest in tumor lineage. Table 2 sets out a lineage-based subdivision of NHL, simplified from the REAL classification, which will guide our discussion here. Distinctions between the various categories depend upon histology, and upon cell

Table 2 Subdivisions of non-Hodgkin lymphoma

markers seen either in tissue sections or dispersed cells. Some of the rarer tumors have been omitted, as have the Ig-exporting B cell lymphomas which are discussed in the next section.

B cell NHL

B lymphoblastic lymphoma is seen histologically to be composed of diffusely distributed immature cells similar to those of pre-B ALL, and the two tumors can probably be regarded as belonging to a single disease spectrum.

B lymphocytic lymphoma can similarly be regarded as a tissue equivalent of CLL, with scattered tumor masses in which infiltrates of small lymphomas efface normal lymphoid architecture. Although the leukemic component is by definition inconspicuous initially, there is a tendency to progress to a final mixed leukemia/lymphoma with widespread tumor throughout nodes, spleen and marrow. Mantle cell lymphoma is a similar tumor which usually behaves more aggressively. It is composed of small to medium lymphocytes which, like those of CLL and B lymphocytic lymphoma, display the surface molecule CD5. The cells have a mainly diffuse distribution, but sometimes congregate around normal follicular centers to form huge mantles. This striking arrangement is apparently imposed by the normal cells upon the neoplastic ones. In this tumor a characteristic translocation between chromosomes 11 and 14 is thought to activate the oncogene *bcl-1*.

Follicle-center lymphomas (follicular lymphomas) are the largest group of NHL occurring in Western societies. Morphologically the cells resemble a segment of that range of lymphocytes which occur normally in the germinal centers of secondary lymphoid follicles. They show a variable tendency to organize themselves into follicles. In general, among the spectrum of follicle-center lymphomas, the larger the cells

and the more diffuse their organization the more aggressive the tumor. In some of the tumors there is a heavy admixture of normal T cells, whose role is obscure.

Follicle-center lymphomas are almost invariably multicentric at presentation. The clinical course varies markedly with the nature of the tumor, but most cases are fairly indolent and 5-year survivals may be expected in more than 50%. Some patients may be left untreated for a number of years, a course chosen by some physicians because, although responses to chemotherapy can be expected, extensive and prolonged remissions are unusual. Waxing and waning of the tumor masses may occur. Eventual progression of the disease is sometimes accompanied by conversion to a more malignant-looking histology, and it is likely under these circumstances that an emerging subclone has suffered additional genomic damage.

The characteristic karyotypic abnormality of follicle-center lymphomas, seen in up to 85% of cases in some series, is a reciprocal translocation between chromosomes 14 and 18. This moves the *bcl-2* oncogene from its normal position on chromosome 18 into the Ig heavy-chain locus on chromosome 14. There follows an overproduction of the *bcl-2* protein, which acts as a suppressor of apoptosis. The cell thereby resists the apoptotic fate of most normal follicle-center cells, a property which must contribute to growth of the tumor. Superimposed genomic damage such as mutation of the p53 suppressor gene has been associated with more aggressive behavior.

Diffuse large B cell lymphomas represent a heterogeneous group of aggressive tumors to which a variety of other names (including centroblastic and immunoblastic) have been given. The cells are larger than those of B lymphoblastic lymphoma and have a high proliferative rate. In some cases a translocation, of variable type, has been reported to activate the oncogene *bcl-6*. The patients often present with a single mass, and can respond well to (and even be cured by) chemotherapy.

Burkitt's lymphoma is a highly malignant extranodal tumor occurring mostly in children. It is composed of B lymphocytes of medium size which resemble follicle-center blasts, but are rarely seen to form follicles. The lymphoma is endemic among children in the tropical uplands of Africa and New Guinea. In these areas the tumor cells regularly contain the EBV genome. In Western societies the tumor occurs only sporadically and is associated with EBV in only a minority of cases. In both situations one sees a characteristic disturbance of the genome in which the *myc* oncogene (or at least its two coding exons) is translocated from chromosome 8 to one of the Ig chromosomes (14, or less commonly 2 or 22).

The high tropical incidence of the tumor probably reflects something like the following chain of events.

1. Early infection with malaria and other parasites leads to a hyperplastic lymphoid system.
2. Infection with EBV also occurs very early in life, possibly acquired via the mother's milk or saliva.
3. The virus promotes mitosis in infected B lymphocytes, but is unable by itself to promote that relentless, environmentally independent growth which constitutes neoplastic autonomy.
4. The parasite-preoccupied lymphoid system cannot generate a sufficiency of the cytotoxic T cells which normally rid the body of EBV-infected B cells.
5. The exuberant B cell mitosis greatly enhances the chance of the chromosomal translocation with *myc* activation which is probably the major determinant of the neoplastic transformation.

Again a superimposed mutation in the p53 suppressor gene may contribute to oncogenesis in some cases, and other genetic lesions have occasionally been described.

Mucosa-associated B cell lymphomas (B cell MALT lymphomas) have been described in gut, salivary glands, thyroid and ocular adnexa. The histology tends to recapitulate that of the normal mucosa-associated lymphoid tissue (MALT), and the neoplastic cells tend to home to mucosal sites. Paradoxically most of these tumors arise in the stomach, which normally contains no organized lymphoid tissue. However such tissue can be acquired as a result of chronic infection with *Helicobacter pylori*, which has been found in association with more than 90% of the lymphomas. Low-grade tumors have been seen to regress after eradication of the bacterium. The association suggests that other causes of chronic mucosal inflammation can also predispose to MALT lymphoma.

Immunodeficiency-associated lymphomas

B cell NHL, in a variety of guises, is the most important tumor to emerge at increased incidence in states of immunodeficiency. Such states are now seen most often in association with AIDS or immunosuppression for organ grafting. The frequency with which NHL emerges appears to reflect the degree of immunosuppression, so that it is commoner following cardiac than renal grafts.

In most cases of immunodeficiency-associated lymphoma there is genomic and antigenic evidence of EBV in the tumor cells. In some cases a polyclonal lymphoproliferation is seen initially, from which a

clearly monoclonal tumor may later emerge. The AIDS-associated lymphomas often exhibit also the *myc*-activating translocations and histological appearances typical of Burkitt's lymphoma.

Despite the EBV association the post-transplant tumors are rarely of Burkitt type. More commonly the histology is of diffuse large B cell lymphoma, often with plasmacytoid cells present. A variety of genomic lesions have been described. Immuno-deficient states in general can also present pleomorphic lymphomas difficult to classify.

T cell NHL

T lymphoblastic lymphoma is a childhood tumor, the tissue-equivalent of T cell ALL with the cells indistinguishable. It tends to involve the thymus, to progress rapidly, and to terminate in leukemia. For reasons entirely unknown it afflicts predominantly boys.

Enteropathy-associated T cell lymphomas are generally seen as jejunal tumors associated with celiac disease. The latter is a malabsorptive state of puzzling pathogenesis, with features of both hypersensitivity (resolution upon elimination of gluten proteins from the diet) and autoimmunity (a strong association with certain major histocompatibility complex (MHC) class II alleles, the presence of reticulinspecific antibodies, and heavy lymphocytic infiltration of the jejunal epithelium). It seems likely that the tumor is preceded by the celiac disease and arises from the infiltrating lymphocytes. The tumor cells are of various sizes, sometimes pleomorphic. Jejunal ulceration and perforation often supervene.

Other T cell lymphomas are often lumped together as peripheral T cell lymphomas. They are a heterogeneous and confusing group, from which a few striking tumors stand out. Angioimmunoblastic lymphoma displays amid the neoplastic cells an expansion of high endothelial venules, the specialized vessels of T cell areas in lymphoid tissue through which lymphocytic migration from the blood occurs. In angiocentric lymphoma the neoplastic cells invade and occlude blood vessels, leading to ischemic necrosis. Anaplastic large-cell lymphoma is marked by a consistent and striking display of CD30, an activation antigen first observed in Hodgkin's disease. The cells are unusually large, have a variable display of T cell antigens, and often involve nodal sinuses and extranodal sites.

Ig-secreting tumors

Logically these tumors could be included among the non-Hodgkin's lymphomas, but clinical features related to their site of occurrence (myeloma) or

consequences of their protein secretion (macroglobulinemia) usually lead to their being considered apart. A secreted monoclonal Ig accumulating in plasma is called a 'paraprotein'. A secreted molar surplus of its light chain, escaping through the glomerular filter to appear in urine, is called 'Bence Jones protein'.

Macroglobulinemia (of Waldenström) is a lymphoma defined by the accumulation of an IgM paraprotein in large amounts in plasma. Pleomorphic small lymphocytes, some plasmacytoid, widely infiltrate lymphoid tissue so as to enlarge the spleen and lymph nodes and displace normal marrow. They are readily detectable in the blood by virtue of their monoclonal surface IgM. The osteolytic lesions seen in myeloma are rare. Typically the secreted monoclonal IgM is present in plasma at $>10 \text{ mg ml}^{-1}$, and can reach much higher levels. This can cause a striking rise in plasma viscosity, with the possible consequences including retinal hemorrhages and cerebral catastrophes. Such risks sometimes merit an emergency plasmapheresis to lower the paraprotein concentration. A bleeding tendency is common and might reflect a variety of paraprotein activities – raised viscosity, binding to clotting proteins, and interference with platelet functions. Other problems, for example cold hemagglutination and polyneuropathy, can be due to an autoantibody activity of the IgM.

Multiple myeloma is a tumor of plasma cells, sited in the marrow. Usually it is highly malignant. The cells spread diffusely throughout the marrow, and also form discrete nodules which erode the surrounding bone. The characteristic, sharply demarcated bone defects are due to osteoclast activation, possibly by cytokines (IL-1 β and tumor necrosis factor β (TNF β)) released by the tumor cells. In about 75% of cases there is an obvious plasma paraprotein (in order of frequency IgG, IgA, IgD, IgE), in about 50% a Bence Jones protein excretion exceeding 500 mg day^{-1} , and in perhaps 10% a clinically significant light-chain amyloidosis (associated with tissue deposition of the tumor light chains or fragments thereof). The plasma protein may be associated with troubles similar to those described for macroglobulinemia, but these are uncommon. More often the problems of this distressing disease relate to bone destruction, renal failure and immunodeficiency. The disease commonly presents with bone pain or pathological fractures. The kidney can be afflicted by hypercalcemia associated with bone destruction, by extensive protein deposition in tubules associated with Bence Jones proteinuria, by infection, and by amyloidosis.

Solitary myeloma, and myeloma at an extra-

osseous site (plasmacytoma) are occasionally seen. The latter form can readily be induced in the peritoneal cavity in BALB/c mice, a study which has made major contributions to Ig genetics and monoclonal antibody technology.

LYMPHOTOXIN

Carolyn A Cuff and **Nancy H Ruddle**, Department of Epidemiology and Public Health, Yale University, New Haven, Connecticut, USA

Lymphotoxin (LT, also known as TNF β) was originally described as a cytotoxic activity present in culture supernatants of activated lymphocytes. Ruddle and Waksman termed the material 'cytotoxic factor'; Granger and colleagues called it 'lymphotoxin'. In addition to its cytotoxic activity, LT appears to play a role in several biological processes. *In vitro*, LT induces gene expression of immune molecules such as major histocompatibility complex (MHC) and adhesion proteins, stimulates B cell growth, acts as an osteoclast-activating factor, and stimulates the replication of human immunodeficiency virus (HIV). *In vivo*, LT plays a critical role in lymphoid organ development, and has also been implicated in the pathogenesis of the autoimmune diseases multiple sclerosis and insulin-dependent diabetes mellitus. LT may also play a role in protection from infection.

It has recently been determined that LT can be produced as either a soluble protein or surface-associated protein. The soluble form of lymphotoxin is composed of three LT α monomers. It is produced after antigen activation of cytotoxic CD8 T cells and the T_H1 subset of CD4 cells. It is also produced constitutively at a high level by several human T lymphotropic virus type I (HTLV-I)-infected cell lines, by

several murine malignant transformed cell lines that represent early stages of B cell development, by human myeloma cells, and by human Epstein-Barr virus-transformed B cell lines. There have also been reports of its production by cells of the central nervous system, including astrocytes. LT α is not generally produced by macrophages. Analysis of the LT α genes and their proteins indicates strong conservation between several animal species with a homology of approximately 70% at the amino acid level of a secreted mature glycosylated protein of approximately 169 amino acids in length. The molecular weight of the LT α monomer is about 25 kDa, while the secreted trimeric complex is approximately 60–70 kDa in size.

In 1991, Browning and Ware and their colleagues determined that LT was expressed on the surface of T cells. Biochemical characterization of this surface form of LT indicated that LT α subunits associated with a 33 kDa type II transmembrane protein whose gene was subsequently cloned and called LT β . The predominant form of the surface LT on T cells is a heterotrimer of one LT α subunit with two LT β molecules (LT $\alpha_1\beta_2$). LT β mRNA is constitutively expressed by lymphocytes with the spleen and the

thymus expressing the highest level of LT β *in vivo*. It appears that LT α expression is required for appropriate assembly and transport of LT β to the cell surface. The LT $\alpha_1\beta_2$ trimer possesses some cytotoxic activity although much less than LT α . It is not known whether an LT β_3 molecule exists and whether it possesses biologic activity.

LT α and LT β are also related to tumor necrosis factor α (TNF α), sharing sequence and structural characteristics as well as a tight genetic linkage. TNF α , LT α and LT $\alpha_1\beta_2$ all bind to members of the TNF receptor family. These receptors are type I transmembrane proteins with cysteine-rich repeats in the extracellular domain. LT α and TNF α both bind to the type I (TNFRI) and type II (TNFRII) TNF receptors that are also referred to as p55 and p75 respectively. As noted above, because of its relatedness to TNF α and its common receptor usage with TNFRI and TNFRII, LT α is also termed TNF β . TNF α , after release by TNF α convertase (TACE), and LT α trimers bind to and cause clustering of the TNFRI and TNFRII receptors, and this clustering is important for transmission of a signal to the target cell. The crystal structure of the LT α trimer with TNFRI indicates that three receptors are bound by each trimer. LT $\alpha_1\beta_2$ binds to the LT β receptor – originally called TNF receptor-related protein. A schematic representation of the TNF/LT ligand receptor system is shown in Figure 1.

Biologic roles

The role of LT α in lymphoid organ development was established through the analysis of mice made deficient in that protein through homologous recombination. LT α -deficient mice are completely devoid

of peripheral and mesenteric lymph nodes (Figure 2) as well as Peyer's patches. Though the thymus appears normal, there is marked splenic disorganization with a loss of T and B cell areas and germinal centers. It has not yet been established whether LT exerts its effects on lymphoid organ development through the secreted LT α trimer or through the surface-associated LT α/β complex. It has been assumed by some authors that LT exerts its effects in lymphoid development as an LT α/β complex because both TNFRI- and TNFRII-deficient mice have normal lymph nodes. This invokes a role for another receptor, which could be LT β R. An alternative explanation is that there is another LT-specific receptor which has not yet been identified. The role of LT β in lymphoid development will be revealed with the analysis of LT β -deficient mice. However, the organization of lymphoid tissue is probably quite complex, involving several TNF family members and their receptors. This is evidenced by the TNFRI-deficient mice who, although they have normal lymph nodes, lack Peyer's patches and germinal centers.

LT also plays a role in the initiation and elaboration of inflammation. LT α mRNA has been detected during several inflammatory processes in humans and mice. Its proinflammatory properties are most clearly demonstrated in a transgenic mouse model in which LT α is expressed in the pancreas under the control of the rat insulin promoter (RIP). These mice contain leukocytic infiltrates around the pancreatic islets – the site of transgene expression (Figure 3). The mechanism of the LT-induced mononuclear accumulation includes induction of adhesion proteins on the surface of endothelial cells that facilitate the egress of leukocytes to the site of transgene expression and may also involve the induction of

Figure 1 Schematic of TNF/LT ligand receptor system.

Figure 2 $LT\alpha$ -deficient mice lack lymph nodes. (A) Lymph node of a normal mouse. (B) The same region of an $LT\alpha$ -deficient mouse that lacks lymph nodes. chemokines that chemotactically recruit lymphocytes.

$LT\alpha$ is a mediator of killing by cytolytic T cells, 'helper-killer' T cells, natural killer cells, and lymphokine-activated killer cells. It is produced by such cells after stimulation by antigen presented by MHC, their natural targets, or high levels of interleukin 2. Other factors made by such cells that also contribute to killing and may synergize with LT to accelerate

Figure 3 Expression of $LT\alpha$ from the rat insulin promoter (RIP) induces a mononuclear infiltration around the islets of Langerhans in the pancreas. (A) Normal islet of nontransgenic mouse. (B) Inflamed islet of RIP- $LT\alpha$ transgenic mouse.

the process include interferon γ (ITNF δ), TNF α , perforin and serine proteases. The ability of LT to induce DNA fragmentation by apoptosis, a characteristic of cytolytic but not antibody plus complement-mediated killing, further implicates it in cell-mediated killing. Through its cytotoxic activity, LT probably contributes to graft rejection and to manifestations of graft-versus-host reactions. LT kills virus-infected target cells more effectively than non-infected cells, in part because of its synergism with IFN γ . This property suggests that a crucial biologic role for LT may include defense against viruses, particularly through eliminating virus-infected cells.

$LT\alpha$ may also contribute towards the pathogenesis of autoimmune diseases. The ability of $LT\alpha$ to synergize with IFN γ and interleukin 1 in destroying β cells of the islets of Langerhans suggests a role in insulin-dependent diabetes mellitus (IDDM). Observations of induction of myelin swelling by LT, its cytotoxicity against oligodendrocytes and its production by cells of the central nervous system *in vitro* and in multiple sclerosis plaques, implicate it in demyelinating diseases. Its role as an inflammatory

mediator also suggests its involvement in such diseases with their prominent mononuclear infiltrates. LT α production is associated with the ability of T cells to transfer experimental allergic encephalomyelitis, a murine model of an autoimmune demyelinating disease. Suggestive evidence for the contribution of LT to autoimmune disease susceptibility in humans comes from genetic linkage studies that demonstrate an association between a polymorphic allele of LT α with increased risk of diabetes.

Gene structure and regulation

The lymphotoxin genes map within the MHC in humans on chromosome 6 and in the mouse on chromosome 17. They map between the complement (class III) genes and class I MHC genes in close proximity to the TNF α locus (Figure 4). The protein products of these LT/TNF genes share 50% identity at the amino acid level and have common structural motifs. These observations suggest that LT α , LT β and TNF α have arisen through a process of gene duplication.

Expression of LT is regulated at several levels. The promoter and 5' negative and positive regulatory elements of the LT α gene have been identified. Positive transcriptional elements include an NF κ B element. LT α expression is also regulated at the post-transcriptional level. A sequence located in the 3'

untranslated sequences of the gene, TTATTAT, has been implicated in mRNA destabilization. LT α mRNA accumulates to high levels in cells in the presence of cycloheximide, suggesting the existence of a labile repressor of mRNA, perhaps a ribonuclease. LT α has a conventional signal peptide. In contrast to TNF α , which can be displayed as a membrane-bound molecule and then released, LT α is transported through the cell and secreted or stored in granules in cytolytic T cells, or forms the LT α / β complex as noted above. The promoter region of LT β shares several features in common with the LT α promoter, including the presence of a NF κ B-binding site, indicating that LT α and LT β expression may be induced by common signals. However, the LT β promoter also contains transcription factor-binding sites that are not contained in LT α , implying that the two genes can also be regulated independently. The lack of lymphoid organs in the LT α -deficient mice indicates that this gene is expressed during development.

Signaling mechanism

At least one of the two molecular classes of TNF receptors of 55 and 75 kDa have been found on most cell types, with the exception of erythrocytes and resting T cells. They bind to LT α with high affinity. Dissociation constants (K_d) ranging between 10^{-9} and 10^{-11} M have been reported. The number of

Figure 4 Genetic map of the tumor necrosis factor/lymphotoxin (TNF/LT) locus in the human MHC. (Reproduced with permission from Ware *et al* (1995) In: Griffiths and Tschopp (eds) *Pathways for Cytolysis*, pp 175–218. Basel: Springer-Verlag.)

receptors found on individual cells range from 2000 to 50 000. Though the presence of a receptor is required for a response to LT α , the number of molecules expressed by a cell does not necessarily reflect its sensitivity to LT α . Nevertheless, susceptibility to killing by LT α can be enhanced by treatment of targets with IFN γ and this does result in increased binding of LT α , presumably due to increased numbers of receptors.

Less is known about the properties of the LT β R. LT β R mRNA has been detected during embryogenesis as well as in the lung, kidney, liver, spleen and lymph node of the adult mouse, and in several tumor cell lines. The expression of LT β R during embryogenesis suggests it may mediate a signal for lymphoid organ development through binding to the LT $\alpha_1\beta_2$ complex. It is also possible that an as yet unidentified receptor for LT α also plays a role in lymphoid organ development.

Several intracellular signaling events have been implicated in the TNF/LT pathway, including protein kinases, ceramide, proteases, lipases and induction of gene transcription. However, since the TNF receptors contain no intrinsic enzymatic activity, it has been difficult to determine the intracellular events that occur following ligand binding. Recently, regions of the TNFR1, TNFR2 and the LT β receptor have been identified that are necessary for the transmission of signal to the target cell. An 80 amino acid region in TNFR1 is necessary for the cytotoxic activity of TNF. This region has been termed the 'death domain' and is also found in other members of the TNF receptor family that mediate apoptosis. An intracellular protein, TRADD, has also been identified that binds to the TNFR1 through the death domain and initiates the cytotoxic activity. TNFR2 and LT β R similarly possess regions in their cytoplasmic tails that bind intracellular proteins involved in the signal cascade. Both of these receptors bind to proteins called TRAFs. The TRAF (TNFR-associated factor) proteins associate with the receptor and form an intracellular complex that activates NF κ B and subsequent gene expression.

In conclusion, the role of LT in biological processes is quite complex and not fully understood. Its expression is required for the development of lymphoid organs and contributes towards the elaboration of inflammatory processes that are essential for clearance of infectious agents. However, LT expression can also be harmful, contributing towards the pathogenesis of autoimmune diseases. It thus appears that the effects of LT *in vivo* may depend upon appropriate expression levels at the correct time in development or during immune responses. The generation of mice deficient in LT α has allowed for the characterization of the role of LT in immune function as well as its contribution towards autoimmunity. Further data with LT β -deficient mice will provide information regarding the individual roles of secreted LT α and the membrane-associated LT α/β complex.

M

MACROPHAGE ACTIVATION

Siamon Gordon, Sir William Dunn School of Pathology, University of Oxford, Oxford, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The modern concept of the 'angry macrophage (Mø)', the immunologically activated cell generated during infection of the host by intracellular pathogens such as bacille Calmette–Guérin (BCG) and *Listeria*, dated from the work of Mackaness and his colleagues at the Trudeau Institute in the 1960s. Whilst T lymphocytes become activated by antigen-specific pathways, their production of Mø-activating lymphokines, later shown by various workers to be mainly interferon γ (IFN γ), results in enhanced antimicrobial activity directed nonspecifically against a range of microorganisms. This interaction between T lymphocytes and Mø lies at the heart of cellular immunity and delayed-type hypersensitivity. Subsequent studies have shown that a specialized antigen presenting cell related to Mø (the dendritic cell), plays a key role in the activation of T lymphocytes by foreign antigens and that T helper lymphocyte subset 1 (T_H1) responses are mainly responsible for Mø activation, whereas T_H2 responses modulate T_H1 and Mø activation. The major antimicrobial products of the activated Mø include reactive oxygen and nitrogen metabolites, and the range of targets can be extended to viruses including human immunodeficiency virus (HIV), and possibly tumor cells. The importance of Mø activation in host defence and pathogenesis of tissue injury has been underlined by experimental 'knock out' of key genes in the above pathway, and in genetic and acquired diseases in humans.

The Mø also plays a central role in innate immunity, in the absence of T cell activation, and interacts with specific antibody to enhance humoral defense mechanisms. The immunobiology of Mø can be compared with that of neutrophils and other myeloid cells, as well as natural killer (NK) cells and cytotoxic T lymphocytes. Some of the differences and similarities of Mø responses compared with those of other cells will be brought out below.

The definition of Mø activation given above is a relatively strict one and there are circumstances where it may break down. For example, microbial particulates and products, especially lipopolysaccha-

rides (LPS), have complex direct and indirect effects on Mø defense functions. Whilst well able to interact with and amplify IFN γ -induced responses of Mø, these agents also 'activate' a range of antimicrobial systems in the absence of IFN γ . Phagocytic stimulation via plasma membrane receptors involving specific antibody (FcR), other opsonins (e.g. complement) and opsonin-independent recognition of particulates profoundly alter the pattern of Mø gene expression, with overlap and differences from the IFN γ -induced modulation associated with immune, T cell-dependent activation. There is marked heterogeneity of the Mø phenotype within the host reflecting intrinsic changes in their differentiation and extrinsic modulation by cytokines and other factors in their microenvironment. The wide repertoire of plasma membrane receptors and biosynthetic responses, combined with extensive endocytic activity and vacuolar specialization, involve a complex set of Mø-specific and nonspecific gene products and signaling pathways which are still far from unraveled. Some simplifying concepts are now, however, well established and will be summarized here.

Principles of Mø activation

Cell differentiation and recruitment result in heterogeneity of Mø function *in vivo* – resident, recruited (elicited or primed) and reactivated Mø

Monocytes enter the circulation after production from hematopoietic stem cells and more committed precursors in bone marrow, a process that is controlled by various growth and differentiation factors, e.g. colony-stimulating factor 1 (CSF-1), granulocyte-macrophage CSF (GM-CSF) and interleukin 3 (IL-3), as well as inhibitors such as macrophage inflammatory protein 1 α (MIP1 α). The monocytes enter many tissues constitutively in the absence of inflammation, and differentiate into mature, nonproliferating, so-called 'resident' Mø populations. These Mø display a nonactivated phenotype; they express various receptors which allow them to interact with

adjacent cellular and matrix ligands at specific locations (**Figure 1**). Their main functions include trophic interactions with other developing hematopoietic cells and the ability to react to local injury and infection by phagocytosis, production of chemokines and vasoactive molecules, and activation of plasma proteinase cascades. These responses initiate inflammation and result in the recruitment of additional leukocytes, including monocytes themselves. Monocytes can be recruited to local sites of inflammation in large numbers, responding to a range of cytokines and other mediators that influence their adhesion to endothelium, diapedesis and subsequent migration. This process involves adhesion molecules (L- and E-selectins, β_2 -integrins and CD31) and chemokines that act on monocytes alone, or also on neutrophils or T lymphocytes. Recently recruited monocytes retain surface and other properties, e.g. type 3 complement receptor (CR3) and major histocompatibility complex (MHC) class II antigens and can be induced to produce a range of secretory products including tumor necrosis factor α (TNF α) and proteinases such as plasminogen activator (PA), that promote inflammation and repair. Once cells have been recruited in this manner, it is convenient to distinguish two types of inflammatory tissue M ϕ depending on their further exposure to IFN γ : those that become 'immunologically primed' or not ('elicited cells'). The immunologically primed M ϕ are able to respond to local surface triggers, e.g. phagocytosis of microorganisms or interaction with LPS, display an enhanced cytotoxic potential and are

thus fully activated for host defense; elicited M ϕ share many properties with activated M ϕ because of their recent recruitment, but do not express high levels of MHC class II antigens or produce the full range of cytotoxic mediators. Other distinguishing features include differential downregulation by IFN γ of mannose receptors, lectins that recognize a range of microbial ligands. Both elicited and activated M ϕ can aggregate and interact with persistent particulates (foreign bodies, microorganisms, respectively) and other host cells to form granulomata. Recruited M ϕ in diffuse or focal infiltrates thus vary in their phenotype, longevity and turnover; it is likely that Fas/Fas ligand, as well as TNF α /TNF α receptors (TNFR I,II), regulate apoptosis and resolution of M ϕ -rich lesions. Resident M ϕ are longer-lived cells, but even terminally differentiated M ϕ such as microglia in the brain, can be induced to express markers of activation by appropriate stimuli. Locally reactivated M ϕ are soon augmented by the influx of larger numbers of freshly recruited monocytes which become difficult to distinguish from pre-existing M ϕ as they all differentiate in a similar microenvironment. Finally, activation is a reversible process, and cells may undergo deactivation.

Two-stage induction of M ϕ activation – a spectrum of priming

As noted, IFN γ -primed monocytes or M ϕ depend on a further local trigger to initiate full expression of cytotoxicity, e.g. a respiratory burst and production of highly reactive oxygen species (**Figure 2**). The

Figure 1 Heterogeneity of macrophages with regard to activation. Resident M ϕ can be stromal, adhering to tissue ligands and interacting trophically with many cell types in their microenvironment, or less adherent, e.g. in serosal cavities. Heterogeneity results from cellular differentiation and extrinsic modulation by cytokines and other molecules induced by interactions of host cells, often macrophages themselves, with foreign antigens, injurious stimuli and pathogens.

Figure 2 Two-stage activation of macrophages. Different stages of resident and recruited Mø require action of IFN γ to become primed. Local stimuli, often microbial products, trigger surface changes and production of cytokines such as TNF α and reactive oxygen metabolites. Neutral proteinases such as PA can be induced by IFN γ and their release triggered by phagocytosis, but are also induced by nonactivating cytokines, for example CSF-1.

requirement for priming by specific cytokines allows subtle control of appropriate gene expression in the Mø, which is biosynthetically more adaptable than neutrophils, for example, which store preformed products or can activate microbicidal pathways directly. T_H1 and T_H2 lymphocytes, NK, dendritic and other local cells, as well as Mø themselves, play a major role in regulation of Mø priming via cytokines (IL-12, IL-18, IFN γ , IL-4/13, IL-10, IL-6, transforming growth factor β (TGF β), IFN α/β) and other mediators (glucocorticoids, prostaglandins); cell surface molecules (e.g. MHC class II/CD4, adhesion molecules such as integrins and ICAMS, and immune accessory molecules such as B-1/B-2) also control hematopoietic and other cellular interactions (Figure 3).

Recent studies have shown that Mø priming and activation cover a phenotypic spectrum of cytokine actions on Mø (Figure 3 and Table 1) in which it is possible to distinguish not only the polar opposites of activation (IFN γ) and deactivation (IL-10), but also an intermediate phenotype, termed alternate activation (IL-4, IL-13). This spectrum of Mø properties is summarized in Table 1 and indicates considerable diversification of function, depending on their roles in cellular versus humoral immunity, inflammation and repair. It is likely that these described phenotypes, which are mainly based on *in vitro* studies, with isolated cells and individual cytokines, coexist *in vivo*, and that the net outcome of Mø activities within tissues will depend on their reciprocal interactions.

Plasma membrane triggers vary widely in their effects

Mø express a wide range of surface receptors for opsonins and direct microbial recognition as well as for migration, adhesion, cytokine responses and cellular interactions (Table 2). These vary considerably in their ability to trigger Mø biosynthetic and secretory responses; e.g. receptor for Fc fragment of immunoglobulin G (FcR) induces a respiratory burst and arachidonate release, whereas CR3 does not, in various experimental models. Other receptors, such as scavenger receptor type A (SR-A), may downregulate Mø responses to LPS, either by competition among different receptors for LPS (SR-A versus CD14, the receptor for LPS-binding protein), or by postmembrane interactions that are not yet clear. Another question that is not fully resolved is to what extent surface ligation and clustering of receptors is sufficient to trigger Mø secretion, compared with ingestion of phagocytic targets. Differential expression by activated Mø of plasma membrane receptor levels, e.g. reduced mannose receptor, may also not correlate with their ability to mediate secretory responses. Finally, there is still little understanding of receptor turnover and changes in intracellular compartments (endosomal, lysosomal) that accompany immune activation. Receptor-mediated endocytosis is strikingly influenced by different cytokines, and receptor molecules can be induced to undergo proteolytic cleavage and shedding as well as degradation by triggering agents.

Figure 3 A somewhat speculative synthesis of interactions among macrophages, microbial agents and other immune cells, resulting in distinctive Mφ activation phenotypes. Initial contact with foreign antigens and organisms may involve Mφ as well as dendritic cells (DCs), which are specialized to present processed antigens to naive T cells. Mφ and DCs both produce IL-12; IL-18; an IL-12-like IFN γ inducing factor, has less defined sources and target cells. The role of different antigen-presenting cells (APCs) in regulating T_H2 versus T_H1 responses is still unclear. IL-6 has recently been put forward as a candidate. Note that Mφ can produce both pro- and anti-activation signals; TNF α influences DC migration and maturation, as well as performing other effector functions. IFN γ and IL-4 have additional cross-inhibitory and self-amplificatory activities.

Table 1 Spectrum of Mφ activation: phenotypic effects of T_H1 and T_H2-type cytokines on phenotype

	T _H 1-type	T _H 2-types		Significance
	IFN γ	IL-4/13	IL-10	
MHC class II	++	+	–	Immune cell interactions
Respiratory burst	++	(–)	–	Cell-mediated immunity
NO	++	(–)	–	Tissue injury
TNF α	++	(–)	–	Proinflammatory
IL-1				
IL-6				
Mannose receptor	–	++	0(+)	Phagocytosis/endocytosis e.g. antigens
Growth	–	+	0	Local growth of Mφ in immune lesions
Fusion	0	++	0	Giant cell formation – granulomata
Growth factor secretion	–	++	+	Healing of lesions

Diverse biosynthetic and secretory responses are protective, as well as injurious, and are tightly regulated

As a result of differentiation, recruitment, cytokine actions and plasma membrane stimuli, there are complex changes in Mφ gene expression and secretory activities (Table 3). Intracellular signaling pathways in Mφ are still poorly understood, as are the roles of myeloid-specific and other transcription factors that regulate gene expression by Mφ in different functional states. Nuclear factor kappa B (NFκB) and related molecules have received much attention,

mostly in simple model systems or cell lines rather than in primary Mφ *in situ*. IFN γ , by itself, induces a range of changes in expression of Mφ-specific and other genes, at the transcriptional level; inducible products such as TNF α , IL-1 β and IL-6 are controlled transcriptionally and translationally, as well as at post-translational stages, e.g. by processing at the cell surface mediated by specific metalloproteinases. Characteristic 3' AU-rich sequences contribute to instability of mRNA of several such inducible cytokines. Products such as lysozyme are more uniformly induced on activated Mφ populations by

Table 2 Selected plasma membrane receptors of activated macrophages

Receptor	Ligand(s)	Functions	Comments
FcR (several)	IgG, IgE	Opsonic phagocytosis, ADCC, release of inflammatory mediators	Ig superfamily FcR can downregulate hypersensitivity
CR3	iC3b, ICAM-1 promiscuous	Opsonic phagocytosis, non-opsonic phagocytosis, migration (?), adhesion, Mø activation	β_2 -integrin. May not signal secretion from Mø, promotes neutrophil apoptosis Essential for granuloma formation
Scavenger receptor (SR-A)	Selected polyanions, LPS, lipoteichoic acid	Endocytosis, phagocytosis, adhesion	Protects host against LPS
CD44		Adhesion, migration	
Sialoadhesin	Lectin: NeuAc α 2,3Gal β 1,3GalNAc on sialoproteins and gangliosides	Interactions with hematopoietic cells including T lymphocytes	IgSF Expressed by stromal and granuloma Mø Downregulated by IFN γ , IL-4, IL-13
Mannose R	Lectin: mannosyl glycoconjugates	Endocytosis, phagocytosis, secretion	Multiple C-type carbohydrate recognition domains Downregulated by IFN γ Upregulated by IL-4, IL-13
Cytokine receptors	IFN γ	Mø priming, activation, induction MHC class II, TNF α , iNOS, respiratory burst	Essential for granuloma formation, resistance to mycobacteria, other pathogens and opportunistic microorganisms
	IL-4	Alternate activation, stimulate MR endocytosis and APC functions	Similar to IL-13
	TNF α	Proinflammatory, cytotoxicity, apoptosis, granuloma formation, antimicrobial activity, DC migration and maturation	Distinct type I (p55) and II (p75) receptors Septic shock and tissue injury
	IL-10	Deactivation, anti-inflammatory, promotes humoral immunity	Autoregulation by Mø and T _H 2 cells. Can induce Mø genes, as well as inhibit
CD14	LPS-binding protein	Transduces LPS signaling activation, TNF α release	GPI-linked Septic shock soluble form

In addition there are receptors for other cytokines, chemokines and adhesion (CD31, selectins, other integrins), proteases, protease inhibitors, peptides and drugs found on monocytes and/or Mø and not well characterized in activated Mø. (See Gordon and Hughes (1997) for further details.)

poorly understood mechanisms, and serve as excellent markers of Mø activation *in situ*, compared with more limited expression of TNF α . Neutral proteinase activities can be enhanced by downregulation of inhibitors, as well as by induction of enzyme gene expression; their function close to the cell surface is promoted by plasma membrane binding sites, and regulated by endocytic uptake, binding to extracellular ligands such as connective tissue proteins, or inhibitors such as α_2 -macroglobulin which limit their activity to pericellular sites.

TNF α is a central cytokine responsible for many of the local and systemic actions of activated Mø. It is essential for granuloma formation and host

defense, but when produced in excessive amounts, e.g. by primed Mø in response to acute LPS challenge, it contributes to septic shock, vascular damage and death. In chronic infections, it may contribute to host wasting and other manifestations of increased catabolism.

Reactive oxygen and nitrogen metabolites play a major role in the ability of activated Mø to restrict a range of intracellular and other pathogens, as shown by studies in mice and humans, and contribute to local tissue damage. Expression of the various components of the NADPH oxidase and I-NOS is independently regulated, although considerable overlap in responses to cytokines, including IFN γ and

Table 3 Selected secretory products of activated macrophages

<i>Product</i>	<i>Function</i>	<i>Comments</i>
Enzymes		
Lysozyme	Antimicrobial	Constitutive <i>in vitro</i> , inducible <i>in vivo</i> ; myelomonocytic and Paneth cells
Urokinase	Plasminogen activation and fibrinolysis, neutral proteinase activation	Inducible by macrophage activation, phagocytosis and cytokines
Collagenase } Elastase }	Connective tissue catabolism	Inducible
Angiotensin-converting enzyme	Pressor	Steroid inducible
Acid hydrolases (many)	Lysosomal digestion	Mainly intracellular
Cytokines		
IL-1 β } TNF α }	Multiple local and systemic host defense functions, e.g. endothelium, leukocytes, connective tissue	Endogenous pyrogens, tissue injury, weight loss. Superinducible
IFN α/β	Antiviral, immune modulation	
IL-6	Acute phase response	
IL-10	Inhibitor proinflammatory cytokines and APC functions	Also product T _H 2 cells
IL-12	Stimulates IFN γ production by NK and T _H cells	
FGF	Fibroblast growth	
TGF β	Inhibitor activation of macrophages and other targets	
GM-CSF	Granulocyte, macrophage and dendritic cell growth and differentiation	
IL-8	Granulocyte chemoattractant	Chemokine family
MIP1 α/β	Chemoattractant, hematopoietic regulator	Chemokine family
MCP1	Monocyte recruitment	Chemokine family
Rantes	Recruitment of monocytes and T _H cells	
Complement proteins		
Most components classic and alternative pathway	Local opsonization and complement activation	Other sources, e.g. liver
Coagulation factors		
Several, including tissue factor	Local initiation and regulation of clotting	Other major sources
Adhesion, matrix molecules		
Fibronectin, thrombospondin, proteoglycan	Localization, migration, modulation of cellular interactions and phagocytosis	Other major sources
Transport proteins		
Transferrin, B ₁₂ -binding protein, apolipoprotein E.	Transport Fe, vitamin, lipid	Other sources
α_2 -Macroglobulin	Proteinase inhibitor	
Bioactive lipids		
Cyclooxygenase and lipoxygenase products of arachidonate	Mediators of inflammation, e.g. effects on leukocytes, small vessels	Macrophage has high-level arachidonate in membranes therefore potent source
PAF	Platelet activation	
Reactive oxygen intermediates		
Superoxide anion, hydrogen peroxide, singlet oxygen, hydroxyl radicals	Killing and stasis of microorganisms and cells by activated macrophages	Tissue injury, modulated by free radical scavengers
Reactive nitrogen intermediates		
Nitric oxide, nitrites, nitrates	Killing, microbial, parasitic, and cellular targets by IFN γ -activated macrophages	iNOS inducible, compared with low levels of NOS constitutive in other tissues.
		Note: NO not readily detectable in human monocyte/macrophage culture systems
Defensins		
Polypeptides	Antibacterial	Produced only by some macrophages as well as PMNs and Paneth cells

Some of these have not been demonstrated as products of immunologically activated versus other simulated M ϕ .
Adapted from Gordon and Hughes (1997).

IL-10, is present. Secretory activities of activated Mø are tightly regulated by multiple external and intrinsic factors. Products of activated Mø such as IL-10 and TGF β , as well as IFN α/β , prostaglandins and antiproteases, all serve to limit injurious Mø activities.

Intracellular pathogens utilize different strategies to subvert Mø activation

Microorganisms, including bacteria, viruses and parasites, utilize different uptake pathways and adopt a range of survival strategies to evade killing by activated Mø (Figure 4). The failure to trigger a respiratory burst may be connected to their survival; once within the Mø, an organism may interfere with maturation of phagosomes, inhibit acidification and fusion with lysosomes, or lyse the vacuolar membranes. IFN γ can reverse some of these processes, even when added after uptake of an organism. The vital role of IFN γ and its receptor in resistance to various infections has been confirmed in mice and humans, including mycobacterial infection of subjects and experimental animals genetically lacking these molecules. It should be stressed that cytokines such as IL-10 that deactivate Mø and thus enhance susceptibility to infections and inflammatory injury, as in inflammatory bowel disease, are also able to inhibit entry or growth of other pathogens, such as HIV-1. It is therefore necessary to define the role of

individual cytokines in Mø 'activation' in relation to challenge by particular organisms.

Activation of Mø can mediate immunosuppression

If Mø are persistently activated by repeated antigenic stimulation, or fail to eradicate an intracellular pathogen, the cells themselves can become refractory to subsequent stimulation. One consequence may be a failure to produce a respiratory burst in response to a further surface stimulus. The mechanisms are poorly understood and include receptor downregulation as well as inhibition of intracellular signal transduction pathways. An *in vitro* example of failure to reactivate Mø to a repeated stimulus is seen after pretreatment with phorbol ester (PMA), which activates protein kinase C irreversibly. Activated Mø through cell-cell and secretory interactions with T lymphocytes and dendritic cells can also mediate immunosuppression. Examples include inhibition by alveolar Mø, via nitric oxide of antigen-induced proliferation of T lymphocytes. Other Mø products (reactive oxygen metabolites, TNF α , prostaglandins) have also been implicated in antigen nonspecific immunosuppression.

Figure 4 Stages of uptake of a hypothetical pathogen by macrophages. Receptors involved in phagocytic recognition are shown, as are potential steps of evasion of host killing mechanisms. Some of the Mø responses are listed. FA-11 (macrosialin, the murine homolog of CD68) is a pan-Mø glycoprotein abundantly expressed in phagosomes. Selected phagocytic stimuli alter the glycoforms of this membrane molecule profoundly, possibly contributing to phagosomal membrane resistance to intravacuolar enzymes and acidification.

Conclusions

Defective or exaggerated activation of Mø contributes to pathogenesis of a wide range of immunological and other diseases. Key molecules involved in this process provide suitable targets for therapy. Many questions regarding the selective expression of Mø genes and their regulation by extrinsic and intrinsic cellular processes remain for further study. The concepts outlined above should serve as a guide for further dissection of this complex process, and its relation to other aspects of Mø function.

MACROPHAGE COLONY-STIMULATING FACTOR (CSF-1)

E Richard Stanley, Department of Developmental and Molecular Biology,
Albert Einstein College of Medicine, New York, NY, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

CSF-1/macrophage colony-stimulating factor (M-CSF) stimulates the survival, proliferation and differentiation of mononuclear phagocytic cells, from the determined but undifferentiated monoblast through to the mature macrophage. It is the primary regulator of the production of these cells, including osteoclasts and also regulates cells of the female reproductive tract. CSF-1 is synthesized by a variety of different cell types, including fibroblasts, endothelial cells, bone marrow stromal cells, osteoblasts, keratinocytes, astrocytes, myoblasts and, under the control of the female steroid hormones during pregnancy, by uterine epithelial cells. It is homodimeric and secreted as an 80–100 kDa glycoprotein or a 130–160 kDa chondroitin sulfate proteoglycan or

is expressed on the cell surface as a biologically active, membrane-spanning glycoprotein of 68–86 kDa.

Both the secreted forms are found in the circulation. The cell surface form is involved in local regulation and the proteoglycan form may be sequestered to particular sites. The effects of CSF-1 are mediated by the CSF-1 receptor (CSF-1R) that is expressed on osteoclasts and tissue macrophages and their progenitors, as well as embryonic cells, decidual cells and trophoblast. Local and humoral regulation by CSF-1 is summarized in **Figure 1**. Autocrine or paracrine regulation by CSF-1 may be involved in the development or progression of myeloproliferative diseases and neoplasms of the ovary, endometrium

Figure 1 Humoral and local regulation by CSF-1. Target cells are labeled in upper case. Spikes on cells reflect relative CSF-1 receptor density.

and breast for which elevated levels of CSF-1 are a tumor marker.

CSF-1 genomic organization, biosynthesis and structure

The genomic organization and biosynthesis of the various forms of CSF-1 are summarized in Figure 2. Only the N-terminal 150 amino acids of the full-length 522 (human) or 520 (mouse) amino acid CSF-1 precursor are required for *in vitro* biological activity. The crystal structure of this region reveals that the CSF-1 monomer has an antiparallel four α -helical bundle/antiparallel β ribbon structure, similar to the structure of other cytokines, e.g. GM-CSF. The CSF-1 dimer is formed by disulfide bonding two monomers end-to-end, yielding a very flat, elongated structure.

The CSF-1 receptor and CSF-1 signal transduction

The CSF-1R is encoded by the *c-fms* proto-oncogene product. The CSF-1R gene is localized to human chromosome 5q33.3 and to mouse chromosome 18. The human CSF-1R gene is 58 kb in length and comprises 21 introns and 22 exons. Exon 1 encodes non-translated sequences and is 26 kb upstream of the signal peptide encoding exon 2. Gene transcription occurs in a tissue-specific fashion from two distinct promoters. Transcription is initiated upstream of exon 1 in placental trophoblast. However, in macrophages it is initiated immediately upstream of exon 2. The receptor possesses a highly glycosylated extracellular ligand binding domain (493 amino acids), a hydrophobic transmembrane domain (25 amino acids) and an intracellular tyrosine kinase domain

(436 amino acids). The extracellular domain of the CSF-1R is characteristic of members of the immunoglobulin gene superfamily and the tyrosine kinase domain is interrupted by an interkinase domain of 73 amino acids.

Signaling by the CSF-1R is initiated by binding of CSF-1 ($K_d = 0.1$ nM), leading to the stabilization of a dimeric receptor–ligand complex, transphosphorylation of the CSF-1R on multiple tyrosine residues, association of several proteins with the receptor and the tyrosine phosphorylation of cytosolic and membrane-associated proteins. Extracellular domain disulfide bonding, further tyrosine phosphorylation and multiubiquitination of the receptor precede internalization and intralysosomal destruction of the receptor–ligand complex. Proteins that associate with the activated receptor include Shc, Grb2, Cbl and the phosphatidylinositol phosphatase, SHIP. The juxta-membrane region of the CSF-1R has been implicated in internalization. The C-terminal tail of the CSF-1R has been shown to negatively regulate signal transduction and its truncation, in conjunction with point mutations in the extracellular domain in the *v-fms* product, leads to ligand-independent signaling and transforming activity.

CSF-1 biology

Circulating CSF-1 is believed to be derived from endothelial cells lining the small blood vessels. Ninety-four per cent of circulating CSF-1 (half-life 10 min) is cleared by CSF-1R-mediated endocytosis and intracellular degradation by Kupffer cells of the liver and splenic macrophages, only 5% being filtered through the kidney. This clearance mechanism represents a coarse negative feedback control on macrophage production, whereby the number of sinusoidally located end cells determines the steady-state concentration of circulating growth factor. In addition, CSF-1 is synthesized locally by osteoblasts and epithelial cells of the female reproductive tract. By virtue of local synthesis of the long-lived cell surface CSF-1 and of localized sequestration of the secreted proteoglycan CSF-1, both these forms may participate in short-range regulation of target cells (Figure 1).

The mouse mutation, osteopetrotic (op), is an inactivating mutation in the CSF-1 gene. While many of the overt phenotypes of the op/op mouse (Table 1) are significantly corrected by restoration of circulating CSF-1, failure to qualitatively rescue several phenotypes by daily injection with human recombinant CSF-1 (e.g. Table 2), indicates that CSF-1 also acts locally. Studies in op/op mice have established the central role of CSF-1 in the regulation of

Table 1 Overt phenotypes of the CSF-1 null op/op mouse

Osteopetrosis due to reduced numbers of osteoclasts
Reduced bone marrow cellularity
Reduced dermal thickness
Female reproductive defects:
Extended estrus cycle
Reduced pregnancy rate
Reduced postimplantation survival
Failure of lactating mammary gland development
Male reproductive defects:
Reduced testosterone production
Reduced mating capability
Reduced numbers of viable sperm
Reduced numbers of tissue macrophages
Reduced auditory and visual processing
Toothlessness
Reduced weight

Figure 2 CSF-1 genomic organization, expression and structure. The CSF-1 gene is localized to human chromosome 1p13–p21 and mouse chromosome 3. The bottom half of the diagram shows the intron–exon structure and four representative human cDNA clones that have been sequenced. Similar mouse clones have been isolated. Exons (1–10) and the transmembrane domain (TM, cross-hatched), are indicated. The 4 kb and 2.1 kb mRNAs arise from alternative usage of untranslated regions encoded by exons 9 and 10, the latter exon encoding putative mRNA instability sequences (AU). The 1.6 kb and 3.1 kb mRNAs are products of a splicing reaction that results in the use of a short form of exon 6. The approximate intracellular proteolytic cleavage sites (arrowheads) and the chondroitin sulfate glycosaminoglycan addition site (GAG) are also shown. The top half of the diagram shows the processing of CSF-1 homodimers encoded by both the short and long coding regions. Striped regions represent those present in the mature secreted or released glycoprotein forms while both striped and filled regions are present in the major secreted proteoglycan form. N-linked (filled arrowheads) and O-linked (open circles) glycosylation sites, the chondroitin sulfate chain (linked, open hexagons) and the transmembrane domain (filled region) are shown.

osteoclast progenitor cell differentiation and tissue macrophage production (Table 2).

Local CSF-1 expression in the mouse female reproductive tract coincides with CSF-1R expression. CSF-1 regulates the estrus cycle, pregnancy rate, postimplantation embryonic viability and branching

morphogenesis of the lactating mammary gland. While CSF-1 is not absolutely required at any stage during pregnancy, it affects many stages and, if assessed by their ability to produce viable offspring beyond weaning, op/op females are almost completely infertile. CSF-1 regulates the development of

Figure 3 Regulation by CSF-1 of target cells that have trophic and/or scavenger roles in tissues.

testicular macrophages that normally contact the testosterone-producing Leydig cells. Associated with an absence of these testicular macrophages, male op/op mice have a low libido, abnormal Leydig cell morphology and reduced testosterone levels.

The expression of the CSF-1R appears to be restricted to mononuclear phagocytes, their progenitors and cells of the female reproductive tract. Thus the pleiotropic nature of the op/op phenotype suggests that one group of target cells, macrophages,

have important tissue regulatory roles. Tissue macrophages that require CSF-1 for their development are found primarily in tissues undergoing rapid morphogenesis or tissue remodeling (Table 2). A current hypothesis to explain the broad biological effects of CSF-1 is that CSF-1 regulates the development of cells that have important trophic and/or scavenger roles for the development and/or function of the tissue in which they reside (Figure 3).

CSF-1 and the CSF-1R in neoplasia

Viral oncogenic forms of *fms* cause feline fibrosarcomas. The 5' end of the CSF-1R is used approximately 20% of the time as an integration site for Friend murine leukemia virus-induced mouse myeloid leukemias. Autocrine regulation by CSF-1 is a characteristic of all irradiation-induced leukemias in SJL/J mice and of some *myc* retrovirus-induced mouse tumors. Circulating levels of CSF-1 are elevated in patients with myeloid and lymphoid malignancies and carcinomas of the ovary, endometrium and breast. In ovarian cancer, elevated levels of CSF-1 in the circulation or ascitic fluid predict a poor prognosis. At least in some cases, the malignant cells themselves coexpress CSF-1 and the CSF-1R, raising the possibility of autocrine/paracrine growth control by CSF-1 in selected human neoplasias.

MACROPHAGE MIGRATION INHIBITORY FACTOR (MIF)

Graeme Wistow, Section on Molecular Structure and Function, National Eye Institute, NIH, Bethesda, Maryland, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Macrophage migration inhibitory factor (MIF) has an important place in the history of molecular immunology. It has the distinction of being the first lymphokine activity described and as such was the forerunner of the whole new field of molecular immunology. In spite of this, MIF itself has been surprisingly elusive. The name MIF is applied to (at least) two major entities, both of which have some difficulties in definition. MIF was first used to describe a soluble lymphoid cell activity associated with delayed-type hypersensitivity (DTH). However the name has more recently been applied to a specific protein and most current references in the literature are to this protein. To what extent these two definitions overlap is not presently clear.

MIF as a lymphokine activity

The earliest definition of MIF was as a DTH-related activity. Using an *in vitro* assay for inhibition of migration of normal macrophages from a capillary tube, a soluble fraction produced by antigen-stimulated sensitized guinea pig lymphoid cells was defined as MIF independently by Bloom and Bennett, and by David in 1966. However molecular definition of MIF presented difficulties. A key problem, which became apparent as the field matured, is that a wide variety of factors including several cytokines, mitogens and toxins can inhibit macrophage migration. Furthermore, different cell types exhibit random migration which may be inhibited by different factors. Indeed, early attempts to characterize MIF led to the identification of multiple size and charge species. Specific cytokines, in particular, interferon γ (IFN γ) and interleukin 4 (IL-4) have been identified with migration inhibition activity.

One approach to defining MIF was to raise antisera against MIF activity fractions produced by human, mouse and guinea pig lymphoid cells. Although different antisera could block the elicitation of a delayed-type skin reaction, or could detect the expression of immunoreactive material in capillary endothelium a few minutes after stimulation by allergen or toxin, it is not clear to what they were actually reacting. When the human 'MIF' monoclonal antibody 1C5 was used by the Sorg laboratory to purify proteins from con A-stimulated human

peripheral blood monocytes, two proteins of 8 and 14 kDa were identified. These were cloned and were named MRP8 and MRP14, for MIF-related protein. MRP8 and MRP14 are calcium-binding proteins with interesting properties, but it is evident that they do not have MIF activity and they are now referred to as myeloid-related proteins.

MIF as a 12.5 kDa protein

The second, modern phase of MIF studies began with an elegant strategy to identify a protein with MIF activity. This employed expression cloning from a human T cell hybridoma. Pools of expression cDNA clones were assayed for MIF activity, eventually leading to purification of a single clone encoding a 115 amino acid, 12.5 kDa protein by Weiser and others. This protein was designated MIF, but its discovery was followed by some confusion in the field. Although several papers describing the activity of recombinant MIF from this source were published, some had to be withdrawn when preparations were found to be contaminated with phytohemagglutinin which is a potent inhibitor of macrophage migration. Adding to the confusion, what later turned out to be the same gene product was identified by Mikayama and others as glycosylation-inhibiting factor (GIF), a factor involved in regulation of the immunoglobulin E (IgE) antibody response.

In spite of this, the 12.5 kDa protein has retained the name MIF and has become the focus of a rapidly growing number of studies from several different laboratories. The protein does seem to have MIF activity, although this may be sensitive to sources or methods of purification or synthesis. For example, MIF lymphokine activity was detected in native rat liver MIF and recombinant mouse MIF, while both native bovine MIF from brain and recombinant human GIF/MIF apparently lacked detectable MIF activity.

So far, there is no evidence for more than one expressed MIF sequence in any species. For example, mouse GIF is identical to the MIF cloned from mouse eye lens and from BALB/c 3T3 cells, while human GIF is identical to human MIF from eye lens and both differ by only one nucleotide in cDNA sequence and one amino acid in protein sequence from the

original human MIF cloned from T cells, which appears to contain a sequence error or cloning artifact.

A pituitary hormone

In an extensive series of papers from Bucala and coworkers, important new immune system activities have been ascribed to the MIF protein. This group first reported the synthesis of MIF in the anterior pituitary gland and its release during endotoxemia and went on to suggest that MIF is a pituitary stress hormone regulating systemic inflammatory responses. They then expanded on the role of MIF by identifying it as a 'counter-regulatory hormone' for the effects of glucocorticoids in the immune system. Glucocorticoids are a natural part of the response to infection or tissue invasion, acting to modulate inflammatory and immune responses. *In vitro*, MIF can oppose the inhibitory effects which these steroids have on tumor necrosis factor α (TNF α), IL-1 β , IL-6 and IL-8 production in stimulated monocytes, while *in vivo* it was shown that MIF is able to suppress the protective effects of steroids in lethal endotoxemia. In terms of the mechanism of the MIF effect, these authors show that when MIF is used to counteract glucocorticoid inhibition of T cell proliferation, IL-2 and IFN γ synthesis is promoted.

Bucala and coworkers have also identified a regulatory role for MIF in the acute respiratory distress syndrome (ARDS). They find that MIF augments the secretion of proinflammatory TNF α and IL-8 in alveolar cells in ARDS patients, an effect which is blocked by anti-MIF antibodies. Interestingly, another recent report from the same group, shows that MIF colocalizes with insulin in secretory granules in the β cells of the pancreas. Neutralization of MIF with antibody reduced insulin secretion while recombinant MIF potentiated insulin release. Antisense MIF RNA expression was reported to inhibit MIF protein synthesis and to decrease glucose-induced insulin release in the INS cell line. A common thread of both these studies is a role for MIF in promoting secretion of other hormones and cytokines.

A mediator of immune privilege

The anterior chamber of the eye is a classic site of immunological privilege. The tissues of the anterior chamber, such as the corneal endothelium and the lens, lack major histocompatibility complex (MHC) class I antigens. This places them at risk of cell-mediated lysis by infiltrating natural killer (NK) cells.

The anterior chamber is filled with a circulating fluid, the aqueous humor, which promotes rapid suppression of NK cell-mediated cytotoxicity of corneal endothelium. This activity resides in a 12.5 kDa protein which was identified as MIF. The NK inhibitory activity of aqueous humor was abolished by MIF-specific antibody while recombinant mouse MIF inhibited NK cell-mediated lysis. These results suggest another novel function for MIF in regulating NK cell-mediated lysis and sustaining immune privilege (Apree *et al*, submitted).

Roles outside the immune system

Aside from its role as a secreted factor in the immune system, there is evidence for an intracellular mode of action for MIF in many cell types. MIF is widely expressed in many tissues regardless of immune status, including immunologically privileged sites such as the lens and brain. MIF was identified as a highly abundant protein associated with cell differentiation in the acapsular, immune-privileged eye lens in the embryonic chick. It was also cloned from human and mouse lens, confirming its identity with MIF from other sources. Northern blots for human and mouse showed that MIF mRNA is highly abundant in many tissues, including lens and brain and MIF protein was also isolated from bovine brain cytosol.

The spatial and temporal pattern of expression of MIF in lens cells as well as in various other organs suggests that MIF may have a general role in cell growth and differentiation. This idea is supported by the discovery by Lanahan and others that MIF is a delayed early response gene. When growth factors activate cell surface receptors, the signal is transduced to the nucleus where immediate early genes, such as *c-myc*, *c-fos* and *c-jun* are rapidly activated. These factors lead to the induction of the second wave, the delayed early genes. MIF is induced in mid-G₁ phase of the cell cycle in mouse fibroblast cells stimulated by serum or by purified growth factors including platelet-derived growth factor (PDGF) and fibroblast growth factor (FGF). MIF induction thus precedes downstream events such as DNA synthesis and cell division. Interestingly, lens cell proliferation and differentiation is thought to be controlled by a gradient of FGF. These and other results suggest that MIF may be part of the growth factor response in several cell types.

The MIF gene

At one time it was proposed that there is a multigene family for MIF-like proteins, which might help to

explain the diversity of properties described. However, it is now clear that the human genome contains only a single gene for MIF, which has been cloned, sequenced and mapped to chromosome 22q11.2. The human gene for MIF is remarkably small for an intron-containing gene; three exons and two introns occupy only 800 bp. In mouse, similarly, there is a single, functional gene on chromosome 10. However, in contrast to human, the mouse genome also contains multiple processed pseudogenes.

MIF as an enzyme

Another contributor to the identity crisis surrounding MIF was a report that MIF is functionally and evolutionarily related to the detoxification enzyme glutathione *S*-transferase (GST). However, it was soon demonstrated that the sequence similarity proposed was not significant. Furthermore, native MIF from bovine brain and recombinant mouse MIF were shown to lack GST activity. From these results and from recent X-ray structural studies, it now seems a relationship with GST can be dismissed.

Nevertheless, a different enzyme relationship for MIF has unexpectedly emerged. This came about with the identification of a rat protein capable of catalyzing an unusual pathway of melanin synthesis, *D*-dopachrome tautomerase (DDT). DDT and MIF are clearly related, albeit distantly. Remarkably, even though MIF shares less than 30% amino acid identity with DDT, it was found that MIF too can catalyze an isomerization of *D*-dopachrome. This is hardly likely to be the physiologically relevant activity of either protein but it does suggest that MIF may exert its effects through an enzymatic mechanism. Interestingly, DDT has precisely the same gene structure as MIF and is closely linked to MIF in both human and mouse genomes. This is certainly consistent with a history of gene duplication and may also indicate some coordination in expression.

The idea that members of the MIF/DDT family are enzymes found additional support from X-ray crystallographic analyses of MIF. This revealed striking structural similarity to two small bacterial isomerases. These bacterial proteins have very little sequence similarity with MIF and DDT and their relationship would not have been predicted from sequence alone. Even so, all four proteins conserve an N-terminal proline residue which has been implicated in catalytic activity.

In the crystal structure, MIF is a trimer, something which was not expected from previous biochemical and biophysical studies. The core structure of each MIF subunit consists of two α helices with an overlying four stranded β sheet. The subunit contains an

approximate two fold symmetry axis, suggesting that MIF arose by duplication of an ancestral unit. Two extensions from the core structure (the N-terminal peptide and a surface loop) contact other subunits in the trimer, forming additional β sheet interactions. Conceivably, flexibility in these loops might allow different multimerization states in solution and perhaps different binding activities.

What is MIF

The original definition of MIF as an activity may not be as useful as it once was. Many factors are now recognized which can influence random migration in different cell types. The focus of most attention has now shifted to a protein which carries on the name MIF, even though this may not turn out to be completely appropriate. MIF does seem to be able to inhibit macrophage migration, but it also has several other, perhaps more important, roles in immunology and in other areas of biology. Does the apparent pleiotropy of MIF reflect distinct separate roles played by the same small protein or are these all aspects of a single, underlying function? Conceivably MIF has a single, central function, perhaps as an isomerase with a key role in cellular differentiation. Indeed, parallels with cyclophilin are suggested. Whether autocrine, purely intracellular or paracrine, MIF may be part of a mechanism to initiate differentiated state responses in many cells. Depending on the cell type, different responses are elicited. In this way, one activity for MIF could be associated with a wide variety of phenotypes.

MALARIA

Jean Langhorne, Department of Biology, Imperial College of Science, Technology and Medicine, London, UK

Anthony A Holder, Division of Parasitology, National Institute for Medical Research, Mill Hill, London, UK

Malaria is a devastating disease caused by protozoan parasites (*Plasmodium* spp.) that have a complex life cycle in a mosquito and a vertebrate host. Human malaria is caused by four species. Each stage of the life cycle is morphologically distinct and many immunogenic proteins are synthesized at each stage. The disease is caused by the asexual stage in the bloodstream. The parasite has a number of ways of evading a protective immune response, but immunity to the parasite and the disease it causes does develop after repeated exposure. Several strategies for vaccine design and development are being pursued.

Characteristics of the organism and its antigens

The four *Plasmodium* species that infect humans are *P. falciparum*, *P. vivax*, *P. malariae* and *P. ovale*. Of these, *P. falciparum* is largely responsible for acute and often fatal malaria, but there is significant morbidity associated with each malaria infection and a

large proportion of the world's population is at risk from the disease. It has been estimated that malaria is a public health problem in areas where 40% of the world's population live and the disease has severe social and economic consequences for these communities. There has been a recent resurgence of the disease due to the abandonment or breakdown of control measures and to an increasing resistance of the vector to insecticides and falciparum malaria to chemotherapy. There are few new drugs for chemotherapy likely to be available in the immediate future. An alternative approach to control the disease, by vaccination, would be an attractive alternative if effective. The potential of vaccines has stimulated considerable research into the immunology of the disease, and has driven attempts to identify antigens that will induce protective immune responses. In addition to studies in humans, several models using nonhuman malaria parasites or human malaria parasites in unnatural hosts have been exploited experimentally; for example, rodent malaria parasites in

laboratory animals have been used to dissect the immune response to the parasite.

When an infected female *Anopheles* mosquito takes a blood meal sporozoites are transferred from the salivary glands and are carried in the bloodstream of the host to the liver where they invade hepatocytes to begin the exo-erythrocytic (EE) stage of development. Each parasite develops through a trophozoite form and then undergoes nuclear division (exo-erythrocytic schizogony) leading to the production of several thousand merozoites which are released and invade red blood cells. The parasite enters by invagination of the erythrocyte plasma membrane and develops within a parasitophorous vacuole. Asexual multiplication occurs in the infected blood cell, each parasite developing through a trophozoite form into a multinucleated schizont. Further merozoites differentiate in the blood stage schizont and are released by rupture of the infected cell, allowing them to attach to and invade further red cells. Red blood cells infected with mature *P. falciparum* parasites are sequestered from the peripheral circulation by cytoadherence to endothelial cells. Some parasites within red cells differentiate into the sexual forms, gametocytes, which are ingested by the mosquito during a blood meal. Gametogenesis occurs within the mosquito gut to yield macro- and microgametes and after zygote formation the resultant diploid parasite develops into an ookinete which penetrates the mosquito gut wall and forms an oocyst. Within the oocyst further sporozoites develop and on release these migrate to the salivary glands of the mosquito, permitting further infection of the mammalian host.

Each stage of the parasite is morphologically distinct, and although many antigens may be shared between stages others are expressed in a stage-specific manner (Table 1). Since protective immunity

appears to be stage specific, the important immunogens are probably the stage-specific proteins. Proteins on the surface of the parasite, in the vacuole that surrounds the intracellular parasite, and in the apical organelles (rhoptries, micronemes and dense granules) that are involved in cell invasion and colonization, as well as those on the surface of the infected erythrocyte and mediating cytoadherence, are of particular importance.

The circumsporozoite protein (CSP) expressed on the surface, and thrombospondin-related anonymous protein (TRAP) expressed in the micronemes of sporozoites appear to mediate homing to the liver. In the liver stage are found antigens unique to this stage, as well as antigens expressed by the sporozoite and asexual blood stage. The mature EE stage merozoites resemble blood stage merozoites both morphologically and antigenically.

Many proteins synthesized by the asexual blood stage have been identified as antigens using antibodies produced during natural infection. Synthesis of many of the proteins is stage specific, for example many merozoite antigens are synthesized during schizogony (the last 18 h of the 48 h intracellular cycle of *P. falciparum*). There are at least eight proteins on the merozoite surface and several of these are derived from a high molecular mass precursor, merozoite surface protein 1 (MSP-1). The apical secretory complex of merozoites, consisting of paired rhoptry organelles and associated micronemes, is involved in red cell invasion and contains a variety of proteins, including the erythrocyte-binding proteins (EBPs) that are involved in cell recognition and attachment. The parasite extensively modifies the host erythrocyte during intracellular development and several proteins appear to function at the infected red cell membrane. Erythrocyte membrane protein 1 (EMP-1) mediates cytoadherence and is expressed on the

Table 1 Examples of protein antigens, their location and stage specificity

Stage	Location	Protein
Sporozoite	Surface Micronemes	Circumsporozoite protein (CSP) Thrombospondin-related anonymous protein (TRAP)
Infected liver cell	Vacuole	Liver-stage antigen 1 (LSA-1) Sporozoite and liver-stage antigen (SALSA)
Merozoite	Surface Micronemes Rhoptries	Merozoite surface proteins (MSPs) Erythrocyte-binding proteins (EBPs) Apical merozoite antigen 1 (AMA-1) Rhoptry-associated proteins (RAPs)
	Dense granules	Ring-infected erythrocyte surface antigen (RESA)
Infected red blood cell	Surface Parasitophorous vacuole RBC cytoplasm	Erythrocyte membrane protein 1 (EMP-1) Serine-rich protein (SERP) Histidine-rich proteins (HRPs)
Gamete/ookinete	Surface	Pfs 45/48; Pfs 230; Pfs 25

outside of the infected cell membrane, while other proteins appear to interact with the cytoskeleton. Several soluble proteins accumulate in the parasitophorous vacuole and on schizont rupture are released into the plasma. Several of these proteins contain extensive stretches of highly repetitive amino acid sequence, and some of these repeat structures are related to each other, so that extensive antibody cross-reactivity is observed. Both EBP and EMP-1 contain host receptor-binding domains, so called Duffy-binding ligand (DBL) domains. EMP-1 is coded by the var gene family and undergoes antigenic variation.

On the surface of gametes and ookinetes several proteins have been identified. Neither of these stages is present in the blood, but the gametes appear to share these antigens with gametocytes. Other antigens are also shared with the asexual blood stages.

Immune responses of the host

As stated above, the malaria parasite is present in the vertebrate host as two distinct extracellular forms (sporozoites and merozoites) and as intracellular stages within hepatocytes and erythrocytes. Several immune mechanisms could therefore control the different parasite stages and it is probable that no single effector mechanism is responsible for protective immunity in natural infection.

The highest numbers of parasites and the most severe consequences of infection are found in young children in areas of hyperendemic transmission of *Plasmodium falciparum*. Older children often tolerate higher parasitemia without overt clinical disease and with increasing age the incidence of both disease and parasitemia decreases. However it is unlikely that even immune adults eliminate all parasites. The reasons for the slow acquisition of clinical immunity are not yet clear but may be related to extensive antigenic variation of parasite molecules on the surface of infected erythrocytes (see below).

Various experimental models have been developed to examine the interactions between the malaria parasite and the host. None is ideal since in many cases the parasite is not a natural pathogen of the particular host. However these models do highlight the principal means by which a vertebrate host can recognize and eliminate a complex protozoan parasite. Not surprisingly, malaria infections stimulate all components of the immune response in humans and experimental animals: CD4⁺ and CD8⁺ αβ T cell receptor (TCR) T cells, γδ TCR⁺ T cells, macrophages, natural killer (NK) cells, B cells and antibody production are all rapidly induced.

The pre-erythrocytic stages of the parasite include

the extracellular sporozoite and the intracellular forms in hepatocytes. Both stages stimulate the immune system. In humans and in models, CD4⁺ and CD8⁺ T cells and antibodies specific for surface antigens of the sporozoite and some liver-stage antigens can be found after infection. The effectiveness of antibodies to surface antigens of the sporozoite such as CSP in preventing invasion of hepatocytes *in vitro* has been shown with *P. falciparum*, and *in vivo* in rodent and simian model infections. However, only a large amount of specific polyclonal or monoclonal antibody is effective in clearing sporozoites. It is therefore likely that antibodies need to be present prior to infection and in high concentrations in order to control the parasite at this stage. In endemic areas antibodies to CSP develop slowly and high titers of antibody are found only in a few individuals despite the development of clinical immunity. This suggests that antibody to CSP may not be a major protective mechanism in naturally acquired immunity. Humans, monkeys and rodents vaccinated with irradiated sporozoites can be protected against sporozoite challenge. This vaccination procedure induces both antibodies and specific T cell responses, and early studies suggested that protective immunity is due to mechanisms other than ant sporozoite antibodies since there was no correlation between the presence of anti-CSP antibodies and immunity to challenge infection. In addition, immunity in vaccinated rodents could be abrogated by the removal of CD8⁺ T cells. The recent availability of gene-targeted mice with a range of defined immunodeficiencies has confirmed that immunity induced by irradiated sporozoites can be mediated directly by CD8⁺ T cells, CD4⁺ T cells and in some cases by γδ T cells. The effector pathway appears to be via interferon γ (IFNγ) and nitric oxide (NO) in most cases, and not perforins, granzymes or Fas/Fas ligand. The specificity of the protective CD8⁺ T cell response in natural infection is uncertain. CD8⁺ T cells recognizing several different sporozoite and liver-stage antigens have been found in peripheral blood of immunized humans and in the lymphoid organs of rodents.

The next stage of the malaria life cycle takes place within erythrocytes (see Figure 1). Merozoites are released from infected hepatocytes and exist for a short period of time as extracellular forms in the blood. The intraerythrocytic forms – asexual replicating parasites and developing gametocytes – are probably subject to the same immune effector mechanisms. However, since distinct proteins may be expressed in the asexual and sexual forms, the specificity of the response may differ. It is unlikely that infected erythrocytes are recognized directly by T cells as the MHC molecules necessary for recognition

Figure 1 The asexual blood stage of the malaria parasite and possible mechanisms of immunity. Merozoites attach to and invade red blood cells (RBC), and develop through the trophozoite form into the multinucleate schizont. The schizont binds to host cells through proteins inserted into the RBC membrane (cytoadherence). At the end of schizogony merozoites are released and invade new erythrocytes. Antibody may bind to the infected erythrocyte (1) or the merozoite (2), leading to phagocytosis or antibody-dependent cell inhibition; block merozoite invasion of RBC (3); agglutinate free merozoites (4); or interfere with cytoadherence (5). It is possible that the intracellular parasite can be killed by nitric oxide or reactive oxygen radicals released by macrophages.

are not present on mammalian erythrocytes. Thus, as far as the immune system is concerned, the entire erythrocytic phase of the parasite cycle is essentially extracellular. On this basis it would be predicted that antibodies and therefore $CD4^+$ T cells are important in protective immunity. In rodent models where components of the immune system have been inactivated by specific gene targeting, it has been shown that $CD4^+$ T cells are crucial for the development and maintenance of a protective immune response. $CD8^+$ T cells and $\gamma\delta$ T cells appear to play only a minor role in controlling acute blood stage parasites. Detailed analysis of the $CD4^+$ T cell response in rodent erythrocytic infections has shown that both malaria-specific T_H1 and T_H2 cells are activated, each with distinct kinetics. T_H1 cells are predominant

during early acute infection and T_H2 cells are the major responding population later in chronic infection. This led to the hypothesis that parasites could be eliminated by antibody-independent as well as antibody-dependent means. Indeed, it has been shown that macrophages activated by $IFN\gamma$, a key cytokine produced by T_H1 cells, and tumor necrosis factor α ($TNF\alpha$), are able to kill intraerythrocytic parasites. Killing is thought to be brought about by toxic mediators such as nitric oxide and reactive oxygen radicals. Although induction of a large inflammatory response *in vivo* can result in control, and in some cases elimination, of blood stage parasites, mice defective in $IFN\gamma$, $TNF\alpha$ and inducible nitric oxide synthase are able to control and eliminate malaria parasites. By contrast, blood-stage infections

in B cell-deficient mice clearly show that B cells are essential for controlling a primary infection and for resistance to challenge infections. Evidence for the role of CD4⁺ cells and B cells/antibody in human infections is sparse. Specific CD4⁺ of both T_H1 and T_H2 type can be measured in immune individuals, but there are no data yet on the kinetics of these different responses, and their critical role can only be inferred from the rodent models. $\gamma\delta$ T cells and, to a lesser extent, CD8⁺ T cells are activated in human infection but there is no evidence for their role. The species- and strain-specificity of protective immunity against blood-stage parasites implies that specific antibody rather than nonspecific cellular effector mechanisms are important. Antibodies specific for a wide range of parasite proteins are detectable in plasma, some with high titer, during the acquisition of immunity. However, to date, there is no single T cell or antibody response that correlates with protective immunity.

The mechanisms by which antibody can effect elimination of blood-stage parasites are several (Figure 1). Antibodies to surface or rhoptry proteins of merozoites or surface molecules of infected erythrocytes will bring about agglutination or lysis (with complement) and may block invasion of erythrocytes or destroy the infected cell. Successful passive immunization of humans using immune IgG works best with cytophilic antibodies suggesting that antibody-dependent phagocytosis or a type of antibody-dependent cellular cytotoxicity or inhibition may be important. Direct evidence for this role in naturally acquired immunity in humans or animal models is still lacking.

There can be pathological consequences of an immune response to the malaria parasite. Tropical splenomegaly is associated with elevated IgM levels and uptake of immune complexes by phagocytic cells in the liver and spleen. It is most commonly found in regions of high malaria transmission. Nephrotic syndrome associated with *P. malariae* infections in children is related to immune complex deposition in the kidney glomeruli. Many of the features of severe malaria such as hypoglycemia, severe anemia and cerebral malaria could be the consequence of a dysregulated cytokine response. Production of cytokines such as TNF α can be induced in macrophages by the action of parasite components released on schizont rupture (malaria toxins). High levels of plasma TNF α in humans correlate with a poor prognosis in cerebral malaria, and neutralization or elimination of TNF α in a rodent model of cerebral malaria abrogates disease. The very pronounced IFN γ response from CD4⁺ T cells and $\gamma\delta$ T cells observed in acute and convalescent human and rodent infections could

augment the inflammatory responses of macrophages and thus contribute to severe disease.

Evasive strategies by the organism

In order to survive in the host, the malaria parasite needs a number of strategies to avoid the immune response. Shedding of the surface coat of sporozoites when complexed with antibodies may be one avoidance mechanism. Selection of peptide sequences on key molecules that lack the correct motifs for major MHC alleles would be a very effective way of ensuring that the molecule is poorly immunogenic. In this regard, it has been shown that human CSP has long regions of repeated amino acids that bind only to a very restricted number of H-2 alleles. Some molecules expressed on the surface of the parasite, on the parasite-infected erythrocyte, or released as soluble proteins, are polymorphic and coded for by a series of alleles containing repetitive structure (e.g. MSP-2). On top of this some proteins (e.g. AMA-1) may be antigenically very diverse due to numerous single amino acid substitutions. MSP-1 is the target of antibodies inhibiting the proteolytic processing of this molecule that is essential for erythrocyte invasion, but other antibodies binding to MSP-1 block the binding of these host-protective antibodies. One of the most important mechanisms of immune evasion may be antigenic variation of EMP-1, mediated by differential expression of the var gene family.

Vaccines

Studies in a variety of experimental systems have demonstrated that it is possible to protect against challenge infection by vaccination. The complexity of the life cycle means that there are several stages that can be targeted by vaccination strategies (Table 2), although a multivalent, multistage vaccine may be necessary. Vaccines directed solely at the sporozoite stage would need to be capable of inactivating all incoming sporozoites if subsequent liver- and blood-stage infection were to be prevented. Similarly, anti-liver-stage immunity would need to be essentially complete to prevent the clinical disease. Vaccination with sexual-stage antigens, either of the gametes or ookinete (which is not normally exposed to the host immune system) is designed to prevent transmission to the mosquito and, therefore, to protect the population rather than the immunized individual. The ideal requirements for all vaccines is to provide sterile immunity but vaccines that are partially effective may be acceptable, for example one that reduces the blood-stage parasitemia below a level at which it induces pathological and clinical effects. Work has

Table 2 Vaccines against different targets will have different outcomes

Target	Effectiveness	Infection	Parasitemia	Disease	Transmission
Pre-erythrocytic stages	Full	+	+	+	+
	Partial	—	—	reduced (?)	—
Asexual blood stages	Full	—	+	+	+
	Partial	—	reduced	reduced	—
Sexual stages	Full	—	—	—	+
	Partial	—	—	—	reduced
Antidisease	Full	—	—	+	—
	Partial	—	—	reduced	—

A fully effective vaccine against pre-erythrocytic stages would prevent infection (+) and all subsequent stages; an asexual blood-stage vaccine would prevent blood-stage parasitemia (+) and abolish disease pathology (+); a sexual-stage vaccine would only affect transmission (—); and a fully effective 'antidisease' vaccine would prevent disease (+), but have no effect on infection, blood-stage parasitemia or transmission. A partially effective pre-erythrocytic-stage vaccine may reduce disease in semi-immune individuals.

focused on defining protein antigens that may form the basis of a synthetic or recombinant subunit vaccine, and on delivery systems such as effective adjuvants or DNA-based strategies. For an effective vaccine it may be necessary to combine different proteins including those from different stages into hybrid molecules or mixtures (with the additional manufacturing and testing constraints that this imposes). The full extent of malaria antigen diversity and the nature of mechanisms for generating it are not defined yet. It will be important to establish whether the slow acquisition of natural immunity to malaria is due to the need for exposure to many antigenic types within the population. In this context the extent of cross-protection against different strains needs to be elucidated for any vaccine product.

There are no vaccines currently available for large-scale use against malaria. Recent studies in human volunteers with a recombinant hepatitis B surface antigen particle containing part of the CSP, together with a strong adjuvant, have shown that high antibody levels and protection against sporozoite challenge can be achieved.

Extensive field trials of SPf66, a polymerized synthetic peptide containing sequences from a number of *P. falciparum* antigens, have shown that vaccination with this product produces no consistent effect on the occurrence of clinical disease and no effect on parasite prevalence or density. Promising results with recombinant proteins based on MSP-1 have been obtained in experimental models. Thus, although some encouraging results have been obtained, much more fundamental research on the basis of immunity to malaria, the developments of assays that correlate with *in vivo* protection, and extensive studies in humans, are needed before it is clear that an effective vaccine is a realistic goal.

MARSUPIAL IMMUNE SYSTEM

Richard H Sutton, Department of Veterinary Pathology, University of Queensland, Queensland, Australia

The Marsupialia are a widely divergent mammalian order which are phylogenetically distinct from Eutheria. It is an order in which the female has two uteri and two lateral vaginae. The young are born at a very early stage of development and continue their growth while permanently attached to a teat, which is usually enclosed within a pouch or marsupium.

Many groups or families of the order have been recognized in both Australia and the Americas. Because the marsupials are born at a very early stage of growth, development in the pouch is akin to fetal *in utero* growth. Therefore, access to the pouch young has allowed study of many aspects of development which is not readily available in the Eutheria.

Studies of the immune system, both anatomically and physiologically, have been limited to only a few of the more than 100 known species. Much of the work has been on four species: the Virginian opossum (*Didelphis virginiana*), the South American short-tailed opossum (*Monodelphis domestica*) and two Australian species, the brush-tail possum (*Trichosurus vulpecula*) and the quokka (*Setonix brachyurus*). These are considered typical of marsupials; it is assumed, as in placental mammals, that the structure and function of the immune system are similar regardless of the species. What differences are present probably reflect different dietary habits and different evolutionary pressures within their respective environments.

The pouch young

Maternal antibody

The very early developmental stage of the newborn pouch young means that they have only basic but essential physiological processes. Most eutherian newborn are immunologically competent at birth but they are antigenically inexperienced. In contrast, marsupials are not only antigenically inexperienced but also immunologically incompetent. Furthermore, they have to survive in a pouch environment which contains potential pathogens. The development of immune competence and the passive protection of maternal antibody are therefore important requirements. The various time stages relevant to immune development are shown in Table 1.

There is no passage of immunoglobulins during fetal life. This is perhaps surprising in view of their immune incompetence at birth. In *Setonix*, as in most of the Marsupialia, the placenta has a yolk sac (choriovitelline)-endometrial attachment; the allantois does not form part of the attachment. The yolk sac-uterine attachment in *Setonix* appears to form a complete barrier to immunoglobulins, even though they have been detected in uterine fluid.

The main exception to this type of attachment appears to be in the bandicoot (*Perameles* and *Isodon* spp.) where there is a true allanto-chorionic placenta in addition to the yolk sac placenta. Neonatal development is comparatively well advanced at birth in the bandicoot as compared to other marsupials. How this relates to immunoglobulin transfer is not known, but studies in placental mammals have shown that where immunoglobulin transfer between mother and fetus prior to birth does occur, there is an allanto-chorionic placenta, such as in primates, or an inverted yolk sac placentation, such as occurs in rodents. In domestic mammals with epithelio-chorionic attachment (horse, cow, pig, sheep), the

placenta is impermeable to antibodies and where the attachment is endothelio-chorionic (cat, dog), there is about 5–10% transfer of the required immunoglobulin.

Once neonates reach the pouch, attach to the teat, and begin to suckle, immunoglobulins are faintly detected in their serum within 24–48 h (Table 1). As in placental mammals, the transfer in the milk is confined principally to the immunoglobulin G (IgG) class, although IgA and IgE classes are probably also transferred. Some variation in the level of maternal antibody being absorbed has been noted, and with *Didelphis* it has been suggested that the passive transfer does not make an important contribution to the immunological status of the pouch young. More observations are needed to confirm this, but it would be surprising if *Didelphis* were markedly different from other species, where the level of maternal transfer is an important contributor to pouch young immunity. Antigenic stimulation of specific antibody production in the mother is followed by a long delay before transfer of the specific antibody to the young. This may reflect the initial IgM response which does not cross the maternal milk. Absorption of antibody from maternal milk is believed to continue until the young leave the pouch (Table 1). This is in contrast to placental mammals, where, for example, maternal

antibody is absorbed by the foal, calf, lamb, and piglet for about 24 h, the dog for 10–12 days, the rat for 21 days and the hedgehog for 41 days.

Pouch environment and development of immunity

The pouch normally contains a wide range of microorganisms which might be expected to be a problem for an antigenically inexperienced and immune-incompetent neonate. However, it has been shown that there is a reduction in the pouch flora of pregnant *Setonix*. It is not clear whether the antibacterial properties of pouch secretions are due to immunoglobulins or other substances. This 'cleansing' process allows time for the adaptation of the pouch young to its environment and the opportunity to become immune competent. In *Setonix*, the gut of the pouch young is first colonized at about 10 days, which is the time at which some immunocompetence is first apparent (Table 1).

The ability to develop and maintain an immune response is dependent on thymic maturation. The Marsupialia include species with thymic tissue in both intrathoracic and superficial ventral cervical locations. The cervical thymus has its origin in the cervical sinus, whereas the thoracic thymus originates in the third and fourth pharyngeal pouches. There are three distinct groupings based on thymic location, namely thoracic only, both thoracic and cervical, and cervical only. The reason for this variation is not clear. Those with two distinct glands are herbivorous, have a small number (1–4) of pouch young and a large deep pouch. These include many Australian species including *Trichosurus* and *Setonix*. Most families that have carnivorous, insectivorous or omnivorous diets have large litters, a shallow or no pouch, a short pouch term and a thoracic thymus only. All the American marsupials, including *Didelphis* and *Monodelphis*, are in this latter group, which also includes *Antechinus*, *Isodon* and *Perameles* spp. from Australia. The only family grouping with cervical thymus glands only are the wombats, *Vombatus* and *Lasiorninus* spp.

The deep-pouched species have a rich and varied bacterial profile, whereas species with only a thoracic thymus have much less diversity in the bacterial flora in the pouch. However, it has been shown that in *Setonix*, the cervical gland plays a definite role in the development of immune responses. Removal of the gland does not cause a compensatory increase in the thoracic gland but removal of the cervical thymus before day 10 and total thymectomy before day 20 depresses the blood lymphocyte count and delays the onset of immune competence. Total neonatal thymectomy does not stop the subsequent development of immune competence in the adult, even though the

development of other lymphoid tissues is delayed following the thymectomy. Functionally, the role of the cervical gland is probably, at least in part, similar to that of the thoracic gland.

Thymic development in the pouch young is very rapid and appears to correspond to the development of immune competence, which occurs very early after entering the pouch. Immune competence of *Setonix* appears to increase in proportion to the development of the cervical thymus, which becomes functional about 30 days before the thoracic gland and reaches full size at about the time the young leave the pouch. However in the American marsupials the thoracic gland reaches maturity at an early age (Table 1). Whether this also applies to the bandicoots (where immunoglobulin transfer across the allantoic-chorionic placenta may occur) or whether development of their thoracic gland is delayed is not known. The cervical gland can develop to a large size and it has been suggested that the size of the cervical thymus would be difficult to accommodate in an intra-thoracic location.

In most instances, detectable antibody is present within 7 days of challenge. Challenge prior to 8–10 days of age is unlikely to elicit a response. The degree or level of antibody response appears to be dependent on the nature of the antigen. Some antigens appear to provoke an adult-like response early in life, whereas others tend to show an increasing magnitude of response in proportion to age; reaching adult levels at the time of leaving the pouch. This would suggest that there is an inverse relationship between the degree of immune response and the presence of maternally derived antibody. Similar findings to this have also been noted in various species of kangaroos (*Macropus* spp.).

The development of cellular immunity appears to parallel the development of humoral immunity. The results of lymphocytic stimulation tests, for example, support the conclusion that both humoral and cellular immunity develop throughout the pouch term and reach full maturity at the end of pouch life.

The adult immune response

Lymphoid organs

Involution of the thymus is similar in its progression to that of eutherian species. The structure and cellular morphology of the spleen, lymph nodes and bone marrow are also similar to those of the placental mammals. A remarkable happening regarding involution of lymphoid organs occurs in the marsupial mice (*Antechinus swainsonii* and *A. stuartii*). Studies have shown that the thymus undergoes involution before the onset of puberty. In the males, the stress

response to breeding leads to involution of the spleen and lymph nodes; the gut being unaffected. At the end of the breeding season, there is an abrupt and absolute mortality of the males in which it is apparent that the involution of organs associated with immunity plays a role. This 'die back' is unique to the species. Demonstration of cytomegalovirus and adenovirus particles in the tissues of many marsupial species in association with stressful situations suggests that there is a fine balance between health and compromised immunity.

Humoral response

There is evidence to support retardation in the initial phases of the humoral response. This is based on observations where the response to an inoculated bacteriophage by a rabbit produced more antibody, more rapidly than *Didelphis*. Similar observations have been made in koalas (*Phascolarctos* spp.), where it is thought to be due to a delay in B cell activation because B cell numbers are present in similar proportion to those in placental mammals. In *Monodelphis* it has been shown that the primary immune response consists almost equally of IgM and IgG. However, in general, the humoral response in marsupials has the primary features that typify an immune response in placental mammals, including the ability to mount antibody-based or immediate hypersensitivity responses.

Cellular immunity

As in eutherian species, the initiation of the ability to mount a cellular response is dependent on the thymus, although there is evidence to support the possibility of differences in the effector mechanisms of marsupials. This has been reported in *Didelphis* and *Setonix*. In the latter, a study has been made of the delayed hypersensitivity response to 2,4-dinitrofluorobenzene from both topical application and intradermal injection. It showed that a more prolonged regime was required to achieve a eutherian-like response following topical application and a longer latent period was observed with the intradermal administration. This reduced delayed hypersensitivity expression, particularly in contact hypersensitivity, has also been shown to occur in *Trichosurus*, where the use of oxazolone failed to induce a contact hypersensitivity. It has been found that the skin of *Trichosurus* has low numbers of Langerhans cells as compared to the guinea pig – the latter had 4–5 times the density. A lack of, or a reduced response to, lymphokines has also been suggested.

The lymphokine responsiveness is of interest because of the many reports of mycobacterial infections in various marsupial species. While most of

these infections have resulted in typical granulomatous reactions characteristic of tubercle bacilli, there have been exceptions. The most important is the infection of *Trichosurus* with *Mycobacteria bovis*. This usually results in a disseminated systemic infection in which granuloma formation, a normal characteristic of the disease, is an infrequent finding. A similar finding is seen in *Didelphis* with *Mycobacteria intracellulare* infection. It has been shown that *Trichosurus* has a cell-based response to mycobacterial antigens, but a study with a specific cytokine, macrophage chemotactic factor (MCF), showed that the *Trichosurus* macrophages did not respond to MCF. This was despite the fact that an MCF was produced by *Trichosurus* macrophages that was effective against macrophages of the guinea pig. This unusual finding requires further investigation, but it may explain why tuberculosis in the brush-tail possum is a disseminated disease.

Conclusions

At birth, the pouch young of the Marsupialia are antigenically inexperienced and immune incompetent. There is, by necessity, a rapid development of immune competence. In many species this is mediated by a rapidly developing thymus in a cervical location. Some species may have maternal transference via the placenta but mostly, maternal antibody transference commences at the time of initial suckling and continues until the young leave the pouch, by which time immune competence is at the adult stage of development.

Adult marsupials have, with some variation, lymphoid organs and responses, both humoral and cellular, comparable to those of eutherian species. Observations have suggested that there may be initial retardation in the humoral response and that aspects of the cellular response may be refractory to some cytokines.

MAST CELLS

Reuben P Siraganian, Receptors and Signal Transduction Section, Laboratory of Immunology, National Institute of Dental Research, National Institutes of Health, Bethesda, Maryland, USA

Mast cells and basophils were first described, by Paul Ehrlich more than 100 years ago, as granular cells that stain metachromatically with basic dyes. Mast cells are found in connective tissues, whereas basophils are present in the blood. Both cells have many similarities, although they are distinct cell types. Both cells synthesize and store histamine, proteoglycans and proteases within their granules and have surface receptors (FcεRI) that bind immunoglobulin E (IgE) with high affinity. The binding of multivalent antigen to this cell-bound IgE results in degranulation and the release of mediators, producing an immediate hypersensitivity reaction. Basophils and mast cells are sparsely distributed in the blood or tissues.

Basophils and mast cells have surface receptors, such as integrins, that mediate binding to other cells and to the extracellular matrix. There are changes in adherence of these cells after stimulation that may not only control their migration and localization at sites of inflammation but also regulate their function.

Characteristics and heterogeneity of mast cells

Mast cells are derived from multipotential stem cells that are in the bone marrow. The precursors enter the circulation and appear as ungranulated lymphoid cells that are CD34⁺, c-kit⁺, Ly-1⁺, CD14[−] and CD17[−]. These precursors undergo differentiation after entering a particular tissue and their phenotypic characteristics depend on the local microenvironment. In mice, microenvironmental factors critical for mast cell development include stem cell factor (SCF, also called c-kit ligand). C-kit is a receptor tyrosine kinase present on mast cells that binds, and

is activated by, stem cell factor which is produced by fibroblasts, both as a cell surface protein and as a soluble secreted product. Mast cells are distributed in connective tissues, often adjacent to blood vessels and beneath epithelial surfaces (e.g. the gastrointestinal and respiratory tracts, and the skin). The mature mast cells do not circulate.

Ultrastructurally, mast cells have many long thin projections which appear as villi by scanning electron microscopy. The nucleus is round; there are some mitochondria but the endoplasmic reticulum and the Golgi apparatus are not prominent (Figure 1). Mast

Figure 1 A rat mast cell. Note the prominent granules. (Electron micrograph kindly provided by Drs Constance Oliver and Celia Jamur.)

cells also contain intermediate filaments and lipid bodies. The granules are heterogeneous in substructural pattern; some have a scroll-like appearance, while others have an amorphous electron-dense matrix.

In rodents there are at least two populations of mast cells: the 'mucosal type' (MMCs), which is considered immature, and the 'connective tissue type' (CTMCs), which is more mature. The CTMCs, as the name implies, are distributed in connective tissues, e.g. peritoneum, lung, skin. These cells stain red with the combined alcian blue/safranin O stain owing to their content of heparin. Their proliferation and differentiation is probably influenced by the fibroblasts in connective tissues (i.e. by c-kit ligand). They have a long lifespan (probably several years) and have prominent granules that contain a large amount of histamine. The MMCs, which have also been called atypical mast cells, are prominent in the gastrointestinal mucosa. They differ from CTMCs in that they stain blue with the alcian blue/safranin O dyes because their granules contain mainly chondroitin sulfate proteoglycan. They are smaller than the CTMCs, contain fewer granules with less histamine, and have a short lifespan (a few weeks). CTMCs and MMCs have a common precursor that matures into the different types, depending on the microenvironment. Even after morphological differentiation, mast cells can transdifferentiate between the two different phenotypes. Interleukin 3 (IL-3) stimulates the proliferation and differentiation of hematopoietic progenitor cells to generate neutrophils, macrophages, megakaryocytes and mast cells. The culture of mouse bone marrow or spleen cells with this factor generates MMCs; the addition of fibroblasts and therefore stem cell factor causes a phenotypic change to the connective tissue type of mast cell. The two types of mast cell express different proteases.

The two types of mast cell respond differently to secretagogues and pharmacological inhibitors of release. Both types respond to IgE receptor-mediated activation. However, the mucosal cells respond poorly to several secretagogues including basic compounds. The two types of mast cell release different arachidonic acid metabolites; the CTMC releases predominantly prostaglandin D₂ (PGD₂), whereas the MMCs release more leukotriene C₄ (LTC₄) and other products of the lipoxygenase pathway.

Two types of mast cells have been identified in human tissues. The majority of the mast cells on mucosal surfaces, such as the intestinal mucosa and lung alveolar wall, contain tryptase (MC_T). In contrast, the majority of mast cells in the connective tissue and in the dermis contain tryptase, chymase and carboxypeptidase (MC_{TC}).

Mediators from mast cells and basophils

The secretory granules of these cells contain preformed mediators that are released when the cells are stimulated. The *biogenic amines*, such as histamine and serotonin, are major components of the secretory granules. Human mast cells contain histamine but not serotonin; however, serotonin is also present in the mast cells of other species, e.g. rodents. Histamine is produced from the amino acid L-histidine by the cytoplasmic enzyme histidine decarboxylase and then stored in granules. Human mast cells contain 2–3 pg of histamine per cell. After histamine is released from basophils or mast cells it binds and activates specific receptors on other cells, such as bronchial and gastrointestinal smooth muscle. This results in contraction of these smooth muscles and in enhanced vascular permeability. Serotonin, or 5-hydroxytryptamine, is formed by decarboxylation of the hydroxylated tryptophan molecule; in rodents it causes edema and plays an important role in anaphylactic reactions. *Neutral proteases* are also a major component of the secretory granules of mast cells. Several different proteases have been found in mast cells, including tryptase, chymase and carboxypeptidase. Tryptase is in mast cells but not basophils. The characteristic metachromatic staining of mast cells is due to the presence of *proteoglycans* in their granules, i.e. heparin or chondroitin sulfate-type that differ in their carbohydrate linkage. Human mast cells contain heparin and chondroitin sulfate E, whereas basophils have chondroitin sulfate A. Proteoglycans are involved in packaging of preformed mediators in granules. Heparin is an anticoagulant and has several other biological effects. A number of other enzymes including β -hexosaminidase, β -glucuronidase, β -D-galactosidase, arylsulfatase, superoxide dismutase and peroxidase are present and released from the secretory granules. Chemotactic factors for eosinophils, neutrophils and monocytes are also released from mast cells or basophils. These include histamine, which is chemotactic for eosinophils, and small and large peptides.

A number of *lipid mediators* are generated after these cells are stimulated. During secretion arachidonic acid is released from phospholipids as a result of the activation of phospholipase enzymes. The arachidonic acid is then metabolized, either along the cyclooxygenase pathway with the formation of the prostaglandins (predominantly PGD₂ but also thromboxanes), or by the lipoxygenase pathway with the formation of the leukotrienes (predominantly LTC₄). Platelet-activating factor is a low molecular weight phospholipid generated from alkyl phospholipids in the cell. These lipid mediators have

a number of potent biological activities. Mast cell lines and basophils synthesize and release *cytokines* when stimulated, including IL-3, IL-4, IL-5, IL-6, IL-8, tumor necrosis factor α (TNF α), interferon γ (IFN γ), several chemokines and granulocyte-macrophage colony-stimulating factor (GM-CSF).

The high-affinity receptor for IgE

There are two types of receptors for IgE on cells: mast cells and basophils have a high-affinity receptor for monomeric IgE (Fc ϵ RI), while other cells (e.g. lymphocytes, eosinophils, macrophages) have receptors that bind IgE with much lower affinity (Fc ϵ RII, CD23). Structurally, the two receptors are different.

The Fc ϵ RI consists of four polypeptide chains; an IgE-binding α chain of 45–60 kDa, a 33 kDa β subunit and a homodimer formed of disulfide linked γ chains. The different receptor subunits are not covalently linked but have some covalently linked lipids that may be important in their association in the membrane. The binding of IgE to Fc ϵ RI is a simple reversible bimolecular reaction with a high affinity and is not inhibited by immunoglobulins of other classes. Generally, IgE from one species binds only to the Fc ϵ RI of the same or closely related species. However, an exception is the binding of mouse IgE to the human Fc ϵ RI. The Fc ϵ RI are distributed diffusely over the surface of the cell and monomeric IgE–receptor complexes are freely mobile in the membrane. There are large numbers of receptors on basophils and mast cells (best estimates are over 10^5 per cell).

Stimuli for secretion from mast cells or basophils

The physiologically important stimulation of basophils and mast cells is through the high-affinity IgE receptor; the IgE binds through the Fc portion of the molecule while the two Fabs are available for interacting with antigen. Activation of the cell is due to bridging of the IgE molecules by antigen. Receptor-bound IgE can also be cross-linked with anti-IgE antibodies or mitogens. Besides Fc ϵ RI, mast cells have Fc γ RII and Fc γ RIII that bind IgG with much lower affinity than the binding of IgE to the Fc ϵ RI. These receptors for IgG may activate or regulate mast cell secretion. Mast cells/basophils can also be activated to release mediators by other secretagogues, some of which act by binding to surface receptors. These secretagogues include C5a anaphylatoxin, formylmethionine-containing small peptides that are related to bacterial chemotactic factors,

members of the IL-8 family of chemokines, the eosinophilic granule major basic protein, the ionophores, phorbol myristate acetate, polycationic compounds (e.g. polymyxin B or compound 48/80) and neuropeptides (e.g. substance P). Some cytokines induce histamine release by binding to IgE on the cell surface. Several lymphokines modulate IgE-mediated histamine release at low concentrations and induce degranulation at high concentrations.

Biochemical mechanisms of mediator release

Mast cells are stimulated to secrete mediators by antigen reacting with IgE molecules bound to receptors on the cell surface. The release is a rapid secretory (necytotoxic) process. Optimal conditions for the reaction depend on the concentration of IgE on the basophil/mast cell surface, the concentration of the antigen and the affinity of the IgE for the antigen. The bridging of two IgE molecules on the cell surface initiates the cell-triggering signal. The cross-linking of a very small proportion of the total surface IgE is sufficient for cell activation (probably bridging less than 100 IgE molecules, representing 1% of the total receptors on the cell surface).

A number of morphological changes occur during mast cell secretion. The bridging of receptors transforms the microvillous surface of basophils to a plicated appearance; the cells spread and become more adherent. The degranulation of human mast cells results in swelling of the individual granules, a change in the electron-dense granular contents and the formation of interconnected granules with the granule closest to the cell surface fusing with the plasma membrane and thus open to the extracellular medium. There are prominent cytoplasmic filaments close to the granules.

Various biochemical events have been recognized during basophil/mast cell activation, either by direct measurements or by the observation of the effect of inhibitors on the release process. The measurement of a biochemical change is the most unequivocal result.

The Fc ϵ RI subunits lack any known enzymatic activity and thus this receptor depends on associated molecules for transducing intracellular signals. The extracellular domain of the α chain of Fc ϵ RI binds IgE, whereas its relatively short cytoplasmic domain probably does not play a role in cell signaling. In contrast, the COOH-terminal cytoplasmic domains of both the β and the γ subunits are important in Fc ϵ RI-mediated signal transduction. The cytoplasmic domains of the β and the γ subunits of Fc ϵ RI contain the ITAM motif (immunoreceptor tyrosine-based

activation motif) that is critical for signal transduction. This motif is also present in subunits of the T cell and B cell antigen-receptor complexes. The γ component of Fc ϵ RI appears to be the essential receptor subunit for signaling cells for secretion.

Many intracellular processes are regulated by the phosphorylation-dephosphorylation of proteins. Protein tyrosine phosphorylation is an early and critical signal for Fc ϵ RI-induced degranulation. Fc ϵ RI associates and activates several nonreceptor protein tyrosine kinases. Lyn, a member of the *src* family of kinases, is associated with the inner surface of the plasma membrane and with the β subunit of Fc ϵ RI in nonstimulated cells. Aggregation of the receptor results in activation of Lyn. This activation may be due to the dephosphorylation of Lyn at its regulatory site by a protein tyrosine phosphatase that may be CD45. The activation of Lyn results in autophosphorylation of Lyn and in the phosphorylation of the tyrosine residues in the ITAMs of both the β and γ subunits of the Fc ϵ RI. Phosphorylation of the two tyrosines in the ITAM causes more Lyn binding to Fc ϵ RI and also renders both β and γ accessible for interacting with SH₂-containing molecules. Tyrosine phosphorylation of the γ subunit appears to be essential for propagating the signal for degranulation. The phosphorylated ITAMs recruit the cytoplasmic tyrosine kinase Syk that binds to mostly the γ subunit of the receptor by its two SH₂ domains. This results in the activation of Syk, its autophosphorylation and in propagation of downstream signaling events.

The activated Syk tyrosine kinase phosphorylates phospholipase C- γ 1 and phospholipase C- γ 2, which results in increased catalytic activity. These phospholipases catalyze the hydrolysis of phosphatidylinositol 4,5-bisphosphate, resulting in the generation of inositol 1,4,5-trisphosphate and 1,2-diacylglycerol. These second messengers release Ca²⁺ from internal stores and activate protein kinase C respectively. Both events are essential for Fc ϵ RI-mediated secretion.

Following Fc ϵ RI aggregation there is an increase in the cytoplasmic calcium concentration due to the mobilization of Ca²⁺ as a result of the binding of inositol 1,4,5-trisphosphate to specific intracellular receptors. This initial rise in [Ca²⁺]_i is followed by the sustained influx of Ca²⁺ from the extracellular medium. The increase in [Ca²⁺]_i regulates Ca²⁺/calmodulin-dependent events. One of these downstream enzymes is calcineurin, a calcium/calmodulin-dependent serine phosphatase that is sensitive to the immunosuppressive drug cyclosporine.

Aggregation of Fc ϵ RI also activates other cytoplasmic protein tyrosine kinases. One of these is Btk (Bruton's tyrosine kinase) which associates with and

is phosphorylated by protein kinase C. Another protein tyrosine kinase is FAK (focal adhesion kinase, pp125^{FAK}), a kinase that is present in many cells and is activated by adhesion. FAK is tyrosine phosphorylated after cell stimulation and may play a role in the late steps of degranulation. The aggregation of Fc ϵ RI also induces the tyrosine phosphorylation of many other proteins.

The early tyrosine phosphorylation events activate the Ras protein kinase cascade. In this pathway the adaptor protein Shc binds to the tyrosine phosphorylated Fc ϵ RI components, recruits Grb2 which in turn recruits Sos (the mammalian homolog of the *Drosophila* son of sevenless). Sos is constitutively associated with Grb2 in a complex that is cytosolic but gets membrane associated after cell activation. Sos is a guanine nucleotide exchange factor that activates Ras to the GTP form by the promotion of guanine nucleotide exchange. Vav also may have similar guanine nucleotide exchange factor activity. Activation of Ras by the dissociation of GDP and the binding of GTP results in stimulation of downstream kinases. Ras is deactivated by GTPase-activating proteins (GAP) which results in the hydrolysis of GTP. In mast cells Ras activates the Raf pathway. Activated Ras binds Raf, a cytosolic serine/threonine kinase, and recruits it to the plasma membrane and results in its activation. Raf then activates Mitogen Activated Protein (MAP)-kinase kinases by phosphorylating it on Ser residues. The MAP-kinase kinases then activate MAP kinase by phosphorylating them on both Tyr and Thr residues. The substrates of the MAP-kinases include transcription factors such as *c-Jun*, *c-Fos* and cytoplasmic phospholipase A₂. Phosphorylation of the transcription factors of the *c-Jun* and *c-Fos* families allows their nuclear migration and the induction of new genes. The Ras pathway thus leads to both the release of arachidonic acid and nuclear events such as the induction of cytokine genes.

The protein kinase C (PKC) family of molecules phosphorylate proteins on serine or threonine residues and are essential transducers of signals for secretion. The RBL-2H3 mast cells contain the α , β , δ , ϵ and ζ isoforms of PKC. After Fc ϵ RI aggregation PKC translocates to the membrane fractions. The β or δ isozymes of PKC isozymes are required for optimal Fc ϵ RI-mediated secretion, whereas the α and ϵ isozymes inhibit the receptor induced hydrolysis of inositol phospholipids. Activated PKC phosphorylates several proteins, including myosin light chain and the γ subunit of Fc ϵ RI.

Cytoskeletal reorganization plays a role in the movement of granules and the degranulation process. These changes are secondary to the rise in

[Ca²⁺]_i, phosphorylation of cellular proteins and/or activation of GTP-binding proteins. Two *ras*-related small GTPases, *rho* and *rac*, appear to play a role in secretion. The cytoskeleton is also involved in the large-scale clustering and capping of aggregated FcεRI.

The activation of phospholipase C and phospholipase A₂ in stimulated cells results in the release of arachidonic acid from cellular phospholipids. The activity of cytosolic phospholipase A₂ is regulated by phosphorylation by MAP kinase and PKC. The arachidonic acid released is metabolized by either the cyclo-oxygenase or the lipoxygenase pathway. The products of the lipoxygenase pathway are the leukotrienes (LTC₄, LTD₄, LTE₄, LTB₄), whereas the cyclo-oxygenase pathway results in the formation of prostaglandin D₂. There is also the formation of some thromboxane A₂ and prostacyclin.

MATERNAL ANTIBODIES

Ann Kari Lefvert, Department of Medicine and Immunological Research Laboratory, Karolinska Hospital, Stockholm, Sweden

The fundamental rule of the immune system is to protect against the numerous potential pathogens which are present in the environment. The memory of earlier invasions of pathogens allows the immune system to mount an early and vigorous response when invaded for the second time. Newborn and young are particularly susceptible to infection as the development of the immune system is incomplete and little is committed to immunological memory. To offset this vulnerability the mammalian young benefits from the mother's experience and the newborn is protected from certain diseases by maternal antibodies that are transferred *in utero* and via the breast milk.

The transferred maternal antibodies can also lead to overt disease in the fetus and newborn child. Examples of this are isoimmunizations and neonatal disease caused by transfer of autoantibodies from mothers having an antibody-mediated autoimmune disease.

There is, however, not only the passive transfer of immunity and the memory of the individual, there is also the memory of the tribe. Early signals reaching the developing immune system strongly influences the functional status of the adult immune network. Such signals are maternal antibodies, self antigens

and external antigens that are present during a critical period. A strong analogy is found in the development of the nervous system. The initial system is genetically programmed and the connectance greater than in the corresponding adult system. The final structure and function depends on the selective enhancement and stabilization of some pathways caused by external stimuli. An imprint of the environment is thus integrated into the initial system. Thus, in individuals with the same basic repertoire, the presence of different self antigens, different maternal immunoglobulins and external antigens will drive the immune system into different functional states. The most important functional effect of this prenatal and neonatal priming is the transfer to the child of maternal immunoglobulins representing the mother's immunological memory, thus making the child's immune system ready to react early and vigorously when meeting a pathogen for the first time.

Evidence for the effect of maternal immunity on the immunological competence of the offspring comes from experiments involving foreign as well as self antigens and antibodies. In the case of foreign antigens both enhanced antibody responses and specific hyporesponsiveness have been reported in the

progeny of mothers making an immune response during pregnancy. The same fundamentally different effects can be caused by maternal antibodies. In contrast, only relative protection against autoimmunity rather than susceptibility to disease has been described in the very few studies made of the offspring of mothers with autoimmune diseases.

Effect of maternal immunity on the child

Transfer of antibodies

In most mammals, the offspring receives maternal immunoglobulins both *in utero* and in the neonatal period via the mother's milk. In humans, transfer of immunoglobulin G (IgG) via the placenta has been detected as early as 38 days gestation. This transfer remains stable until week 17 and then progressively increases towards term. Only IgG antibodies pass the placenta. The transport process involves binding of an intact Fc portion to specific placental membrane receptors, typically of the Fc γ type III variety (CD16) that contain binding sites for the Fc region of IgG as well as antigenic determinants that can be recognized by the antigen-binding site of IgG. These receptors have low affinity for aggregated or complexed IgG. Their affinity is strongest for IgG1 and IgG3, less for IgG4, least for IgG2 and none for IgM and for IgA. The receptors are especially concentrated on the area of the syncytiotrophoblast that makes direct contact with the maternal circulation. The selectivity of the transport process also relates to the target epitopes (e.g. neutralizing antibodies to measles reach a higher relative concentration in the fetus than mumps antibodies), to the antibody avidity and to its functions (especially opsonic activity). There is a close positive correlation between the concentrations of IgG in the child and that found in the mother, the IgG concentration in the newborn child usually being 10–15% higher. An exception is children born to mothers with very high IgG levels in whom the transport mechanism of the placenta limits the transfer and the child will be born with relatively less IgG than the mother. This limited placental transfer may interfere with transfer of tetanus-specific antibodies from vaccinated mothers to the child. It has also been implicated as a cause of neonatal susceptibility to infection in children in the Third World.

The newborn is usually resistant to certain infections if the mother has had the disease. Examples are viral infections such as rubeola, rubella and measles. The time of the greatest susceptibility to such infections occurs when the passively transferred antibodies have decreased and before the child's own immunoglobulin production is sufficient, in humans at 3–6 months of age. Induction of antibodies in

pregnant women by vaccination can also prevent infections such as diphtheria, pertussis and tetanus in the newborn.

In rodents, the breast milk is the quantitatively most important source of antibodies. The pups have special receptors for IgG in the intestine that take up IgG from the milk to the fetal circulation.

In humans, the colostrum and fresh breast milk contains an abundance of host-resistance factors, both specific and nonspecific. The most abundant immunoglobulin in these fluids is secretory IgA. The concentration of IgA is highest in colostrum and peaks during the first 3–4 days postpartum. A fully breastfed child receives about 0.5 g of secretory IgA per day. This secretory IgA protects the infant from a variety of enteric and respiratory pathogenic microorganisms. Antibodies to bacteria, viruses, parasites and fungi have been identified. Most of the antibodies present in breast milk are directed against organisms that colonize, or are pathogenic to, the gastrointestinal and respiratory tracts. The antigenic exposure resulting in milk IgA antibodies seems thus to occur primarily in the gut and in the lungs. From these locations lymphocytes which switch to become committed to IgA production home to the sites of secretory IgA synthesis, such as the intestinal mucosa and the salivary and the mammary glands. By this elegant mechanism, the enteromammary link, the baby is provided with mother's milk which contains secretory IgA antibodies against all the microbes in the mother's milieu which the infant is also likely to meet.

Human milk also contains IgG and IgM as well as secretory IgA but in lower concentrations. The IgG antibodies in milk, especially the IgG3 and IgG4 antibodies, may be directed against a number of *E. coli* antigens. The distribution of IgG subclasses in colostrum and milk differs from that in serum, and milk contains more IgG1 and less IgG2. This increase of the milk IgG1 may provide an additional protection against viral infections.

Protection in the breastfed infant against *Vibrio cholerae*, *Shigella* and *Campylobacter* relates to the content in the mother's milk of secretory IgA antibodies against these pathogens. Protection against severe rotavirus diarrhea is also suggested as is protection against *Helicobacter pylori* infections. Studies have also shown that breastfeeding can prevent otitis media and this protection may relate to the fact that the milk secretory IgA may decrease nasopharyngeal colonization with *Haemophilus influenzae*.

Also factors other than immunoglobulins may protect against infections. Lactoferrin, an iron-binding protein, that functions in a bacteriostatic manner by depriving microorganisms of iron, is abundant in

breast milk and organisms with high iron requirements such as coliforms and yeast are inhibited by this substance. Lysosyme, an enzyme that is synthesized by macrophages in the milk, can damage the cell wall of certain bacteria and also has anti-inflammatory properties.

In the presence of human milk, certain bacteria cannot adhere to retropharyngeal cells as they otherwise do. This effect is due to the presence in human milk of receptor analogs. These structures are identical to cell surface components which various microorganisms use for attachment to epithelial cells as an initial step in the establishment of an infection.

In rats the IgG antibodies against food antigens in the milk inhibit an IgE response in the offspring against the same antigens after weaning. There are some data also in humans that high levels of antibodies to cow's milk in the mother's milk, are associated with decreased risk to develop cow's milk allergy.

Breast milk contains macrophages, T and B lymphocytes, neutrophils and epithelial cells. Lymphocytes in the breast milk produce IgA and various cytokines such as interferons that may provide protection against viral infections. The response of milk T cells to some antigens is different from that of peripheral blood T cells. Milk T cells are usually highly reactive to organisms invading the gastrointestinal tract. Interestingly, the milk T cells seem to have the phenotypic and functional characteristics of memory T cells and contain twice as many T cells bearing $\gamma\delta$ receptors as peripheral blood.

There is also evidence that human milk contains agents that may work as immunomodulators. Retrospective epidemiologic studies suggested that breastfed infants are at less risk of developing type I diabetes mellitus, lymphoma and Crohn's disease later in childhood. In the case of diabetes there is evidence suggesting that antibodies to a 17 amino acid peptide from bovine albumin cross-react with a protein (p69) found on the surface of certain pancreatic islets. It is also of interest that maternal renal allografts have a better survival in individuals who were breastfed rather than those that were not breastfed.

The human fetus is capable of synthesis of antibodies of all isotypes starting at the 15–20th week of gestation. The fetus produces small amounts of IgG antibodies but very little IgM and IgA antibodies, unless challenged with an antigen, i.e. an intrauterine infection. In such cases, especially the IgM level can reach that of adults. Production of antibodies in the fetus *in utero* occurs also in response to maternal immunization. Immunization of pregnant women with tetanus toxoid has been shown to induce an active antibody response in the

fetus, probably at least partly due to transplacental passage of the antigen. Maternal anti-idiotypic antibodies against antimicrobial antibodies may induce synthesis of antibodies against the same microbes in the fetus. This may be the explanation for the presence of antibodies against antigens not available to the fetus, such as antibodies against poliovirus in children to immunized mothers.

Priming of the immune system by maternal antibodies

Maternal antibodies have dual effects. They supply both passive protection and they prime the immune system of the child for subsequent exposure to antigen. In mice and rats, neonatal priming with idiotype and anti-idiotypic antibody protects from subsequent infection with the original microbial antigen. This has been demonstrated for *E. coli* K13, *Trypanosoma rhodesiense*, rabies virus, hepatitis B virus, *Mycobacterium leprae*, influenzavirus and *Plasmodium falciparum* malaria.

Little is known about the immune priming by maternal antibodies in humans. Antibody responses to vaccination with pertussis-diphtheria-tetanus vaccine are greater in babies who had passively transferred antibodies from the mother at birth. There is also evidence for immune priming in babies to mothers with *Plasmodium falciparum* malaria. Circumstantial evidence, such as the devastating effect of introduction of new microbes in populations previously spared, is likely to reflect the importance of prenatal immune priming.

The acquisition of self tolerance occurs during ontogeny of the immune system and in experimental animals the effect of antibodies during the fetal or neonatal period is usually a long-lasting suppression. Fetal or neonatal injection of antiallotype or anti-idiotypic antibodies commonly leads to the disappearance of the target allotypes and idiotypes. Neonatal BALB/c mice given small amounts of anti-idiotypic antibody are chronically unresponsive to immunization with the original antigen. Similarly, antiallotype-induced allotype suppression in rabbits and chickens and anti-isotype isotype suppression in mice have been demonstrated.

In analogy to the priming for infections described above, also enhancing effects by administration of antibodies can be demonstrated. The net effect depends on the amount of the antibody injected or transferred and the stage of development of the fetus.

Early observations of maternally induced tolerance in human disease showed that rhesus-negative women were less likely to produce anti-D antibodies when pregnant with a Rhesus-positive fetus if their mother was rhesus-negative. The long-term survival

of maternal renal grafts was also better than for paternal grafts. In a study of hyperimmunized patients with broadly reactive leukocyte antibodies waiting for a renal transplant, it was shown that 50% of the patients had not formed antibodies against the noninherited maternal class I antigens, whereas antibodies against noninherited paternal class I antigens almost always were present.

Very little information is available concerning the effect of maternal active autoimmune disease. The offspring of mice with autoimmune hemolytic anemia induced by immunization with rat red blood cells were unresponsive to subsequent immunization with the cross-reactive self antigen on mouse red blood cells but not to foreign antigens on rat red blood cells. Paternal disease did not affect the progeny. In another study on rats, the progeny of mothers with experimental autoimmune encephalomyelitis during lactation were resistant to subsequent induction of the disease.

In humans, the relative resistance to insulin-dependent diabetes in children to diabetic mothers as compared to children with a diabetic father is likely to represent the same maternally induced tolerance induction to autoantigens during ontogeny.

Diseases caused by maternal antibodies

Isoantibodies

Antibodies against blood group antigens can cause hemolytic disease of the newborn. The mild hemolytic disease caused by ABO incompatibility occurs almost exclusively in children of mothers belonging to group O. It is the most common antibody-mediated perinatal disease with an incidence varying from 1 to 5% in different ethnic populations. Though laboratory findings of this disease are common, only a minority of the children require treatment.

Before the discovery that hemolytic disease due to rhesus-incompatibility and anti-D antibodies could be prevented by postnatal treatment of mothers with anti-D antiserum, the incidence was between 0.6 and 0.7%, with 60% of the children requiring therapy and a fetal mortality of around 12%.

Thrombocytopenia and neutropenia in the newborn child can also occur due to maternal isoantibodies, but these disorders are much rarer than hemolytic disease.

Autoimmune diseases

Transfer of maternal IgG antibodies across the placenta may give rise to autoimmune diseases also in the fetus and newborn child. Such disease is most

often transient, disappearing as the maternal antibodies are catabolized. These neonatal effects have been observed in a range of autoimmune diseases and the materno-fetal model has been crucial in confirming an autoimmune basis of many such disorders. The materno-fetal model also provides a unique, naturally occurring, experimental system which should be valuable in gaining an understanding not only of the pathogenic process in autoimmune diseases but also of the priming influence of the maternal immunity on the developing immune system. The incidence of fetal or neonatal disease in children to mothers with antibody-mediated autoimmune diseases is not 100% but ranges from 5 to 60% for the most common disorders, indicating that factors other than the maternal antibodies are of importance. Recent data in human autoimmune disease suggest that the fetal contribution to expression of neonatal disease may be a very important factor.

Autoimmune hemolytic anemia

In this disease, autoantibodies and complement are bound to erythrocytes, causing lysis or adherence to macrophages followed by phagocytosis. The autoantibodies are either of IgG type and commonly directed against rhesus antigens, or cold agglutinins, mostly IgM, directed against the I or i blood group antigen. The risks to the fetus are hypoxia due to maternal anemia and hemolysis induced by maternal IgG antibodies. Incidence of severe neonatal hemolytic anemia has been estimated at 35–40% in the offspring of affected mothers.

Autoimmune thrombocytopenic purpura

The disease is relatively common in women of child-bearing age and characterized by thrombocytopenia caused by autoantibodies, usually of the IgG isotype. The antibodies bind to circulating thrombocytes that are either lysed or are destroyed by phagocytosis. The level of platelet-bound IgG correlates well with severity of the disease. The condition was early recognized as a cause of neonatal thrombocytopenia. The maternal levels of thrombocytes and platelet-bound antibodies do not correlate well with the fetal platelet count which makes blood sampling from the fetus necessary to predict the outcome. The incidence of the neonatal disease is 60%, with a mortality of about 15%, principally due to intracranial hemorrhage. Neonatal thrombocytopenia also occurs in mothers cured by splenectomy, since the relevant antibodies are still present in the mother.

Thyroid diseases

Autoimmune thyroid disorders are common in

women of childbearing age. There is a whole spectrum of autoantibodies that affect thyroid function, ranging from antibodies that stimulate the TSH receptor to those blocking TSH binding to the receptor. In Graves' disease the net result of the antibody action is usually a stimulation of thyroid hormone production and hence hyperthyroidism. Graves' ophthalmopathy, which sometimes occurs in the absence of thyroid disease, may be due to autoantibodies reactive with orbital antigens.

Stimulating and blocking antibodies may interact with the fetal thyroid and depending on their affinity and relative titers, lead to varying alterations in thyroid function. Fetal and neonatal hyperthyroidism occur in 5% of women with Graves' disease. It is commonly present before birth and then manifested as fetal tachycardia. In rare cases, autoantibodies blocking the binding of TSH can cause transient hypothyroidism. The duration of untreated neonatal thyroid diseases is generally less than 3 months – the survival time of maternal immunoglobulins. The neonatal disease occurs also in children of treated, euthyroid women.

Hashimoto's thyroiditis is an inflammatory disease characterized by antibodies against thyroglobulin and thyroid peroxidase. Transferred maternal antibodies can cause transient impairment of thyroid function, and even permanent residual damage to the child thyroid gland has been described.

Diabetes mellitus

Diabetes mellitus type I is caused by an autoimmune attack on the pancreatic β cells. The disease-specific antibodies against insulin and against islet cells usually precede overt diabetes by years, by which time islet cell antibody has generally disappeared. Although the islet cell antibodies react with the cell surface to inhibit insulin secretion, β cell destruction is probably mediated mostly by T cells. This is supported by the lack of transplacental antibody effects in maternal diabetes. Transient neonatal diabetes with a pattern entirely in accordance with a causative transplacental factor, has, however, been described in babies of mothers who have no history of diabetes. Since the autoantibodies in diabetes usually disappear with the start of overt disease, it is conceivable that only women in a prediabetic stage can give birth to affected babies.

In diabetes, it has for long been known that the relative risk of developing diabetes is about three times higher for the child of a diabetic father than for the offspring of a diabetic mother. This difference is not caused by a selective loss of diabetes-susceptible fetus or by perinatal death. Thus, exposure *in utero* to an affected mother can protect a fetus

from developing diabetes later in life. Induction of immunologic tolerance to the autoantigens of the β cells is a plausible mechanism for this protective effect.

Myasthenia gravis

Myasthenia gravis is caused by antibodies against the acetylcholine receptor of the skeletal muscle endplate. These antibodies disturb neuromuscular function, leading to increased muscular fatiguability. In experimental myasthenia gravis in rabbits, the autoantibodies cause degenerative changes and immaturity of the receptors in the offspring. Children of myasthenic mothers are in rare cases born with contractures of the joints due to immaturity of the muscles caused by underdevelopment of the neuromuscular junction.

About 12% of children of myasthenic mothers develop neonatal myasthenia with neuromuscular symptoms noted usually on the first day of life. The duration of clinical disease is usually 1–6 weeks. The transmission defect as determined by electrophysiological examination may persist for several months, indicating damage to the acetylcholine receptors.

In most infants with neonatal myasthenia gravis the half-life of the acetylcholine receptor antibodies is longer than the expected 20 days. In contrast, healthy children have a much shorter half-life than expected for the maternally transferred autoantibody. A correlation between the absence of anti-idiotypic antibodies against the receptor antibodies and neonatal disease has also been described. The short half-life in healthy children is conceivably due to an anti-idiotypic response in the child, leading to faster elimination of receptor antibodies and/or suppression of antibody-producing cell clones.

In myasthenia, the fetal contribution to the disease may be important. Analysis of the idiotypic specificity of the receptor antibodies has shown fetal production of antibodies bearing idiotopes not found in the mother. This triggering of autoantibody production in the child may explain the persistence of receptor antibodies and the electrophysiological signs of disturbed neuromuscular function in children with neonatal disease.

There is also evidence for a long-term effect of the maternal antibodies on the antibody repertoire of the child. Low concentrations of receptor antibodies are commonly found in healthy children of myasthenic mothers with an incidence of around 40%. In such children studied at 2–2.5 years of age, the majority, 70%, have an idio type repertoire not found in the mother. Thus, in this case, exposure to idiotopes on maternal immunoglobulins leads to tolerance

induction and suppression of the corresponding clones in the developing child.

Nonorgan-specific autoimmune diseases

Within the group of nonorgan-specific autoimmune diseases there are several multisystem diseases with overlapping features. Such diseases are systemic lupus erythematosus, progressive systemic sclerosis, mixed connective tissue disease, rheumatoid arthritis, Sjögren's syndrome and dermatomyositis. Generally, these diseases are characterized by involvement of multiple organs and a wide range of immunological abnormalities. Production of autoantibodies against a variety of nonorgan-specific antigens is the rule. These autoantigens include single- and double-stranded DNA, histones and non-histone nuclear proteins and RNA-protein complexes such as Sm, U1-RNP, Ro(SS-A) and La(SS-B). Antibodies against cell surface structures and certain phospholipids are also common. Tissue damage is in most cases related to immune complex deposition and only a few of the autoantibodies have been proven to be of pathogenic importance.

A complex of neonatal manifestations may appear in children to mothers with certain of these antibodies. The neonatal lupus syndrome includes transient lupus dermatitis, hepatosplenomegaly and hematologic abnormalities such as thrombocytopenia and hemolytic anemia. The most serious and only permanent manifestation of this syndrome is closely correlated to maternal Ro and La antibodies. These antibodies are directed against soluble tissue ribonucleoprotein antigens. The presence of especially Ro antibodies is associated with congenital complete heart block due to diffuse endomyocardial fibrosis and fibrosis and calcification of the cardiac conduction system, especially in the region of the atrioventricular node. Antibodies reactive with fetal cardiac tissue are present in a significantly higher proportion in mothers of babies with congenital complete block than in controls. Anti-La antibodies especially have been shown to cross-react significantly with laminin and to bind to the surface of fetal myocytes but not to normal adult hearts. This suggests that the cross-reaction between laminin and La but not Ro may be important and that laminin may act as a target for specific maternal autoantibodies and contribute to the pathogenesis of congenital heart block at a critical stage during fetal cardiac development. Mothers of affected children always have Ro or La antibodies, but the reverse is not true, suggesting that other factors are necessary to induce the condition. Also in neonatal lupus syndrome there may be a fetal contribution to the pathogenesis. Idiotypes of DNA antibodies different from that of

the mother have been found in newborns. The hearts of affected children show deposition of immunoglobulins of isotypes not transferred from the mother, suggesting that autoantibody synthesis is also occurring in the child.

Some manifestation of the neonatal lupus syndrome is seen in the offspring of 7–38% of mothers with Ro/La antibodies. Complete congenital heart block has a lower incidence in these children, probably around 5%. Many mothers delivering infants with the neonatal lupus syndrome are asymptomatic but more than half will eventually display autoimmune disease.

The presence of antibodies against certain phospholipids is common in patients with nonorgan-specific autoimmune diseases. These antibodies are associated with thrombosis, thrombocytopenia and recurrent fetal loss. Two clinically important antibodies are recognized – the lupus anticoagulant and the cardiolipin antibody. Both these antibodies belong to the broadly reactive family of phospholipid antibodies and bind to phosphodiester bonds in negatively charged phospholipids. They sometimes have identical binding sites but can also show fine differences in the antigen specificity.

The lupus anticoagulant inhibits phospholipid-dependent coagulation tests. Such antibodies are found in about 25% of patients with systemic lupus erythematosus and to varying extents in other autoimmune disorders. There is a prominent clinical association with thrombosis and recurrent fetal loss due to extensive infarction and necrosis of the placenta. A study has shown that more than 90% of untreated pregnancies in women with lupus anticoagulant are lost.

Antibodies against cardiolipin are present in about 50% of patients with systemic lupus erythematosus. The association between recurrent fetal death and cardiolipin antibodies is clear, but not as strong as for lupus anticoagulant.

Intervention by maternal antibodies

The maternal immune status deeply influences the immune capacity of the newborn, both by passive transfer of immunity and by priming of the developing immune system. The use of vaccination of pregnant women to protect the child is already much used and will be developed to encompass more pathogens in the future.

A more specific approach to detection of disease and to specific therapy in antibody-mediated diseases of the newborn will follow the unraveling of the mysteries of self tolerance. Recognition of precipitating factors and manipulation of the immune system by

modulation of specific antibody responses and induction of tolerance may in the future lead to specific immunological therapy of both the mother and the child.

MATURATION OF IMMUNE RESPONSES

Edward W Voss, Department of Microbiology, Chemical and Life Sciences Laboratory, University of Illinois, Urbana, USA

Maturation of adaptive immune responses involves a comprehensive system development of multiple components at both the protein and cellular levels in response to the introduction of foreign antigen (immunogen) into an immunocompetent host. Maturation of an immune response commences with recognition of a pathogen or foreign material, either particulate or soluble, and subsequently proceeds through a progressive manifestation of both specific humoral and cellular immune responses mounted to eliminate the material. Stimulation of humoral immune responses leads to production, secretion and circulation of soluble antibodies which react specifically with the antigen. Induction of cell-mediated immunity involves various immunological reactions mediated by stimulated T lymphocytes and can include direct interaction of the T cells with infected or transformed cells. Maturation events associated with cellular immune responses are in general less well defined than those related to humoral responses.

Specific antibody induction is analogous to the basic stimulus–response phenomenon: antigen acts as a stimulus to which cells constituting or mediating the immune system respond in various ways. Physiologically, the ultimate goal of the immune response is antigen elimination from the host. This is achieved efficiently through various maturation processes which are perceived as occurring in two stages. During the first stage, exogenous antigens (primarily proteins) are encountered by phagocytic cells and

internalized within intracellular endocytic vacuoles via various pathways. Antigen uptake, processing and presentation is usually a function performed by various cells including macrophages, dendritic cells and B cells. Antigen is subsequently processed prior to extracellular presentation to the appropriate T lymphocytes in a specific substructural form (peptide) consistent with a stimulus effect. In the humoral response the second phase is evidenced by production and secretion of soluble antibody molecules. Specific interactions of antibody protein products with antigen may promote a second burst of phagocytic activity, digestion, and accelerated antigen clearance because immune complexes function efficiently as reinitiators of the immune response.

Antigenic stimulation produces cellular mitogenic and differentiation effects. Antigenic stimuli are classified as either T cell-dependent or T cell-independent and the immune maturation process differs with the two types of stimuli. T cell-dependent antigenic stimulation usually involves foreign proteins which initiate a complex pathway involving T and B lymphocytes. The cellular pathway involves significant amplification because each activated cell can subsequently stimulate multiple cells at each step in the pathway. Amplification is also due to the fact that antigen-stimulated T and B lymphocytes display an accelerated rate of cell division concomitant with a progressive lymphocyte-to-plasma cell differentiation process. When antigenic stimuli are mediated

by antigens involving T helper cells, the resultant B cell immune response is characterized by immunoglobulin M (IgM) to IgG isotype switching and affinity maturation (which reflects somatic mutation events). In contrast, T cell-independent stimulation results in an immune response deficient in both class switching and affinity maturation. T Cell-dependent responses result in enhanced hyperimmune responses upon restimulation while T cell-independent responses conform to undulatory patterns of similar magnitude upon re-exposure to the antigen.

Processed and presented antigen can also be recognized by the T cell receptor-CD8 complex of cytotoxic T cells. Responding cytotoxic T cells are stimulated to divide and differentiate as certain genes are sequentially activated. The dividing cytotoxic T cells eventually differentiate into separate memory and effector T cell populations. The effector T cells destroy target cells such as malignant tumor cells.

Immune competent hosts are capable of producing different antibodies to millions of foreign antigens and a diverse array of antibodies even to the same antigen. Antigenic stimulation usually involves activation of several different lymphocytes (both B and T) which recognize each epitope but may vary in terms of fine specificity and affinity. After antigenic stimulation, blast cells appear in lymphoid organs. These immature plasma cells or triggered B lymphocytes divide rapidly and the progeny eventually become morphologically and functionally specialized. The phenomenon of multiple lymphocytic stimulations results in a polyclonal immune response to the antigen. Polyclonal activation is not always accomplished instantaneously and can occur via sequential events indicative of maturation processes.

Immunoglobulin class switch characteristic of the maturation process is transacted at the gene level. Antigen-stimulated B lymphocytes produce IgM molecules for a relatively short period of time followed by IgG molecules. Since this occurs within the same cell, and is a function of immunoglobulin gene arrangement, the process is referred to as class switching and is a critical parameter in the maturation of a T cell-dependent antibody response. IgG molecules are the principal component of the memory response, although some IgM is synthesized during secondary immune responses. IgG antibodies are of significantly higher affinity than IgM molecules, which represents another characteristic of the mature immune response.

The temporal-dependent affinity increase in the antigen-specific antibody population is a random somatic hypermutation process which occurs during rapid cell division within the variable domains of antibody molecules. The process results in an

increase in the average affinity of the heterogeneous antigen-specific antibody population. Humoral immune responses which exhibit affinity maturation characteristically differ depending on the biochemical nature of a T cell-dependent foreign antigen.

The extent of affinity maturation also depends on the individual host- or species-related immune response genetic repertoire. Proliferation of B cells secreting high-affinity antibodies is regarded as a selective cellular competition for limited amounts of antigen. Thus, clonal expansion of antibody-secreting lymphocytes results from selection pressures exerted by decreasing antigen concentration, with preferential proliferation of specific B lymphocytes possessing relatively high-affinity Ig receptors, particularly in the germinal centers of secondary follicles. Low-affinity clones are probably eliminated by cellular apoptosis.

It is evident that the phenomenon of affinity maturation is a dynamic process at the antibody level, but the extent to which the average affinity increases depends on the biochemical nature of the antigenic determinant. The biological ramifications of affinity maturation are numerous. High-affinity antibodies are most protective in various diseases caused by pathogenic microorganisms. High-affinity antibodies also provide long-term immunity, since low concentrations of high-affinity antibodies remain effective as protective antibodies. In immune responses characterized by significant affinity maturation and achievement of highly avid antibodies, the corresponding antibody titer determined in various assays can be attributed more to intrinsic affinity than to antibody concentration. The latter is consistent with the *in vivo* protective effects of high-affinity antibodies.

Maturation results in immunological memory which is a unique feature of the adaptive immune response. Immunological memory represents a mechanism whereby the immune system responds faster and more efficiently to subsequent exposures to an antigen relative to the first exposure. Immunological memory postulates that a large number of primed cells with preferential selection for high affinity are stored due to the rapid cell division which occurred as a result of the initial antigenic stimulus. The larger number of cells represent a reserve that the immune system relies upon to provide long-term protective immunity. Sustenance of immunological memory represents successful completion of the various factors involved in maturation of the immune response.

In recent years, a new facet involved in immune response maturation has been identified based conceptually on the immune system acting in the context of control mechanisms as a regulatory network of

interacting antibodies and lymphocytes. In general terms, the immune response to an antigen can be regulated via intricate and complex networks. These Ig networks are based on responses to antibody-variable domains in both the nonliganded (idiotype) and liganded (metatype) states. In addition, an auto-immune response against circulating immune complexes (presumably of high affinity) exists which assists in the clearance of immune complexes. This response, termed the antimetatype response, is specific for the unique conformation of the variable domains of antibodies in the liganded state. Sequential events that occur after the initial antigen stimulation and lead to a regulatory dynamic equilibrium (at the protein and cellular levels) are considered part of the immune response maturation processes.

MEMBRANE-ASSOCIATED CYTOSKELETON: ROLE IN REGULATING IMMUNE CELL FUNCTION

Lilly Y W Bourguignon, Department of Cell Biology and Anatomy, School of Medicine, University of Miami, Miami, Florida, USA

The term 'membrane skeleton' refers to the array of cytoskeletal elements which underlie and interact with the plasma membrane and/or internal membrane vesicles of cells. All eukaryotic cells, including lymphocytes, contain such a membrane skeleton system. Based on a variety of cytochemical, biochemical and molecular biological evidence, it has been established that transmembrane linkages occur between intracellular actin/myosin filaments and surface

receptors. It is believed that the formation of a direct connection between the membrane skeleton and transmembrane proteins may be one of the earliest events to occur following ligand–receptor interaction. This entry focuses on the molecular interactions between certain lymphocyte membrane proteins and two membrane-associated cytoskeletal proteins, fodrin (a spectrin-like molecule) and ankyrin, during lymphocyte signal transduction and cell adhesion.

Interaction between CD45 and the cytoskeleton in lymphocyte activation

The leukocyte common antigen CD45 is a transmembrane glycoprotein tyrosine phosphatase that is extensively expressed on all nucleated hematopoietic cells. The extracellular region of CD45 shows remarkable polymorphism among different leukocyte lineages. The CD45 protein contains an extracellular domain for the ligand binding, a single transmembrane domain and a large cytoplasmic domain that displays an intrinsic protein tyrosine phosphatase (PTPase) activity.

Certain cytoskeletal proteins (e.g. fodrin and spectrin) have been found to be closely associated with CD45 as a complex. Recently, the fodrin-binding domain of CD45 has been mapped by deleting various portions of the cytoplasmic region, followed by the expression of these truncated cDNAs using an *in vitro* transcription/translation system. The results of these experiments indicate that the CD45's fodrin-binding domain resides between amino acids 825 and 939. Construction of a fusion protein encoding the region between amino acids 825 and 939 shows that this particular sequence itself is sufficient for fodrin binding. Further analyses indicate that the amino acid sequence ($^{930}\text{EENKKKNRN}^{939}\text{S}$) in CD45 has good sequence homology with the spectrin-binding domain found in the MSP1 glycoprotein of the malarial parasite. Biochemical studies, using binding competition assays and a synthetic peptide containing the sequence ($^{930}\text{EENKKKNRN}^{939}\text{S}$), support the conclusion that the sequence between amino acids 930 and 939 is a critical part of CD45's fodrin-binding domain. Further studies indicate that this sequence is also involved in the fodrin-induced upregulation of CD45 PTPase activity. Therefore, it is suggested that fodrin binding to this domain is required for the onset of CD45-mediated signal transduction and leukocyte activation.

Interaction between CD44 and the cytoskeleton

CD44 isoforms belong to a family of glycoproteins known to comprise a variable extracellular domain, a single spanning 23 amino acid transmembrane domain and a 70 amino acid cytoplasmic domain. These molecules are expressed in a wide variety of tissues and cells. In humans CD44 is encoded by a single gene on chromosome 11p which contains 19 exons. Most often, alternative splicing occurs between exons 5 and 15, leading to an insertion in tandem of one or more variant exons (v1–v10, or exons 6 through exons 14 in human cells) within the

membrane proximal region of the extracellular domain. The variable primary amino acid sequence of different CD44 isoforms is further modified by extensive N- and O-glycosylations and glycoaminoglycan (GAG) additions. CD44 isoform expression has been shown to be closely correlated with malignancy of lymphoid cells.

The most common hematopoietic form, CD44s (CD44 standard form), contains exons 1–4 (N-terminal 150 amino acids – extracellular domain), exons 5, 15 and 16 (membrane proximal 85 amino acids), exon 17 (transmembrane domain), and a portion of exons 17 and 19 (C-terminal 70 amino acids – cytoplasmic domain). The extracellular domain of CD44s binds specifically to certain extracellular matrix (ECM) molecules such as hyaluronic acid (HA) – the major extracellular glycosaminoglycan found in mammalian ECM. CD44s–HA interaction has been shown to induce intracellular signal transduction events, cell aggregation, cell proliferation, cell migration and cell adhesion. The cytoplasmic domain of CD44s (approximately 70 amino acids long) is conserved in most of the CD44 isoforms and is clearly involved in the binding of cytoskeletal proteins such as ankyrin. The ankyrin binding site(s) is expressed at a very early stage in the biosynthesis of CD44. Furthermore, the binding interaction between CD44 and ankyrin is highly specific and regulated by several factors including protein kinase C-mediated phosphorylation, palmitoylation and GTP binding. The fact that ankyrin preferentially accumulates underneath lymphocyte CD44 capped structures suggests that the formation of an ankyrin–CD44 complex is related to ligand-induced lymphocyte activation.

Furthermore, the ankyrin-binding domain of murine and human CD44 has been mapped using deletion mutation analyses followed by expressing in the eukaryotic cell systems. The results of these experiments indicate that the ankyrin-binding domain resides in the cytoplasmic domain of CD44 (i.e. amino acids 306–320 in mouse CD44, and amino acids 304–318 in human). Most importantly, CD44's ankyrin-binding domain is required for HA-mediated binding, cell adhesion and signal transduction.

Interaction between Ca^{2+} channels and the cytoskeleton

Cytoskeletal proteins are known to be important participants in multiple functions involving cell regulation. Because the cytoskeletal network (e.g. microfilaments, microtubules and intermediate filaments) can potentially form a physical link

between the plasma membrane, organelle membranes and nuclear membrane, it has been suggested that they are involved in transmitting important regulatory signals during cell activation by agonists. Recently, it has been found that inositol 1,4,5-trisphosphate (IP₃) receptor (a Ca²⁺ channel required for internal Ca²⁺ release), and the cytoskeletal proteins such as ankyrin, are preferentially accumulated within ligand-induced lymphocyte capped structures. The binding between ankyrin and the IP₃ receptor appears to be very specific. Further analyses indicate that the amino acid sequence, 'GGVGDVLRKPS', in the IP₃ receptor shares a great deal of structural homology with the ankyrin-binding domain located in certain well-characterized ankyrin-binding proteins such as the cell adhesion molecule, CD44. Biochemical studies, using competition binding assays and a synthetic peptide identical to 'GGVGDVLRKPS' (a sequence detected in rat brain IP₃ receptor (amino acids 2548–2558) and mouse brain IP₃ receptor (amino acids 2546–2556)), indicate that this 11 amino acid peptide binds specifically to ankyrin (but not fodrin or spectrin). Furthermore, this peptide competes effectively for ankyrin binding to IP₃ receptor-containing vesicles and/or purified IP₃ receptor; and it blocks ankyrin-induced inhibitory effects on IP₃-binding and IP₃-mediated internal Ca²⁺ release in mouse T lymphoma cells. These findings suggest that this amino acid sequence, 'GGVGDVLRKPS', which is located close to the C-terminus of the IP₃ receptor, resides on the cytoplasmic side (not the luminal side) of IP₃ receptor-containing vesicles. This unique region appears to be an important part of the IP₃ receptor ankyrin-binding domain and may play an important role in the regulation of IP₃ receptor-mediated internal Ca²⁺ release during lymphocyte activation.

In addition, the ryanodine receptor (another type of Ca²⁺ channel required for internal Ca²⁺ release) is found to be closely associated with ankyrin. Biochemical analysis indicates that specific, high-affinity binding ($K_d = 0.075$ nM) occurs between the ryanodine receptor and ankyrin in lymphoid cells. Most importantly, the binding of ankyrin to the Ca²⁺ release vesicles significantly blocks ryanodine binding and ryanodine-mediated inhibition of internal Ca²⁺ release. These results suggest that the cytoskeleton plays a pivotal role in the regulation of Ca²⁺ channel (e.g. IP₃ receptor and ryanodine receptor)-mediated internal Ca²⁺ release during lymphocyte activation.

Taken together, these findings strongly suggest that the membrane-associated cytoskeletal proteins, such as fodrin and ankyrin, play a pivotal role in regulating early signal transduction (including Ca²⁺ mobilization and tyrosine phosphatase activity) and cell adhesion required for lymphocyte function.

MEMORY, IMMUNOLOGICAL

Kevin J Horgan, UCLA Division of Digestive Diseases, UCLA School of Medicine, Los Angeles, California, USA

Memory is a critical property of the immune system which has evolved to provide efficient defense against pathogens. For centuries it has been known that a state of resistance was frequently induced during an illness so that it was unusual for an individual to become symptomatic a second time. This was particularly evident for diseases like smallpox with its characteristic skin rash. This state of resistance

became known as a state of 'immunity' (*l. immunitas*, 'to be exempt from duty to the state'), and was subsequently widely exploited in smallpox infection using a procedure known as 'variolation'. An individual at risk was inoculated with material from smallpox pus or scabs to deliberately induce a mild infection which then conferred immunity against the normally severe natural infection.

Since then the conceptual understanding of immunization has progressed and vaccination has had a major impact on public health. The aim of vaccination is generally to induce immunological memory which is as robust and sustained as that induced by natural infection. The longevity of immunological memory is illustrated by the measles epidemic which affected the entire population of the Faroe islands in 1846 except for a few elderly people who had been previously infected 65 years before. This natural experiment also effectively demonstrated that re-exposure to the measles virus was not necessary to maintain protective immunity for many years.

It is clear that the basis for immunity is the capacity of the immune system to retain a memory of the original infective agent so that on re-encountering it, the immune response is enhanced, usually preventing overt infection and averting a fatal outcome. However, the consequences of immune memory are not invariably beneficial. For example a second infection with dengue virus is usually more severe than the first. A noninfectious example of the detrimental effects of immunity is sensitization to an allergen.

Immunological memory, like neurological memory, is multifactorial and the precise molecular and cellular mechanisms are only partially understood. Both major compartments of lymphocytes, the B cells and T cells, contribute to immunological memory. Ultimately, immunological memory exploits efficient interactions of memory T cells with memory B cells.

T cell memory

Consider, for example, a simplified scenario of the development of contact hypersensitivity to an antigen such as poison ivy. At the first exposure to the antigen, the immunologic response is usually modest and may be barely discernible. Nevertheless, at the second or subsequent exposure, severe inflammation may result from a similar amount of antigen. The cell type which mediates this kind of delayed type hypersensitivity (DTH) is a CD4⁺ T cell which recognizes the foreign antigen introduced to the skin and produces inflammatory cytokines. At the first exposure, the individual has only naive T cells. Naive T cells probably are not sensitized in the skin at the site of antigen entry, but rather in the regional lymph nodes. Such nodes are ideal sites for the initial stimulation for several reasons:

1. There are specialized antigen-presenting cells (APC) in the skin (Langerhans cells) which take up antigen and transport it to regional lymph nodes. In the lymph node antigen is 'presented' very efficiently by these specialized APCs (either

by transfer from the Langerhans cells or further differentiation of that cell).

2. Naive T cells are not present in skin (and most other tissues) in significant numbers, but circulate profusely through regional lymph nodes where the microanatomy facilitates encounter of T cells with APCs. The large number of naive T cells migrating through the lymph node and the high frequency of T cell encounters with APCs assures effective stimulation of the rare naive T cell specific for the particular antigen such as poison ivy.
3. The lymph node provides a specialized micro-environment which facilitates the stimulation of naive cells. *In vitro* studies suggest that naive T cells need special conditions for stimulation and the milieu within the lymph node is rich in the appropriate adjunctive signals derived from cytokines, specialized extracellular matrix or cell surface ligands.

During a primary response, the T cell stimulation may not be evident because it is occurring in the regional lymph nodes rather than the site of antigen exposure: the skin. The specific naive T cells, which are small, are undergoing activation, clonal expansion and differentiation into primary effector cells. Therefore, what had been rare cells become more abundant, by at least several orders of magnitude. The activated effector cells enter the circulation and migrate to the site of original antigen exposure where several mechanisms are employed to deal with the 'infectious agent'. These include lysis of infected cells, local release of cytokines and production of T cell-dependent antibodies. Within a few days the amount of antigen has diminished significantly and the immune response becomes quiescent. The effector T cells are now redundant and most disappear as a result of cell death by means of apoptosis. Importantly, some effector cells survive and become memory cells. A fundamental question is why most effector cells die via apoptosis. Their elimination is probably triggered by the acquisition of sensitivity to ligation of apoptosis-inducing molecules such as CD95 (Fas) and loss of contact with critical cytokines required for growth.

Because of the huge diversity of T cell receptors, and the complexity of typical antigens, each antigen can typically be recognized by multiple rare T cells. Those which expand most efficiently will become the predominant memory cells. The naive T cells with the highest antigenic affinity will preferentially expand. This, together with the increased expression of adhesion molecules, is probably the main reason

that memory T cells have higher affinity for antigen than naive T cells.

T cells differentiate from a surface phenotype characteristic of naive cells, to a surface phenotype characteristic of memory/effector cells. These surface changes alter the way the T cell interacts with its environment. Of particular importance are changes in levels of expression of adhesion molecules. Expression of multiple adhesion molecules is increased as the naive cell becomes a memory/effector cell. Such changes profoundly change the rules of cell-cell interaction which influence migration as well as stimulation. Also, intracellular regulatory pathways are also altered as a T cell becomes a memory/effector cell.

During a subsequent rechallenge with antigen, overt skin inflammation occurs. This results from an infiltration of various inflammatory cells into the area which is initiated by specific T cell recognition. Memory T cells migrate through skin in modest numbers. Recognition of antigen on an APC in skin by a single memory T cell may be sufficient to initiate the cascade of events which constitute the inflammatory response. The memory T cell is easy to trigger via its antigen-specific receptor. Consequently, the nomadic memory T cell moving through skin is poised to respond efficiently to antigen. The ability of memory T cells (much more than naive T cells) to migrate into normal tissue reflects their increased expression of adhesion molecules which enables them to bind endothelium. This memory cell influx is amplified during the inflammatory response when cytokines produced by T cells (e.g. interferon γ (IFN γ) and tumor necrosis factor α (TNF α)) induce expression of adhesion ligands on endothelial cells (such as VCAM-1) to which memory cells bind preferentially. Thus, the dramatic difference between the primary response and the rechallenge in this clinical situation is largely determined by differences between naive and memory T cells. In the immune individual there is a new population of memory T cells for the specific antigen, which occur at higher frequency, can migrate into tissue and can be triggered more readily.

How does the individual maintain memory over decades? Two distinct mechanisms are likely to contribute. First, individual memory T cells may have an extremely long lifespan. Data from humans with severe radiation exposure suggest that individual T cells can persist without dividing for decades. Second, there are specialized mechanisms for retaining antigen in lymphoid organs for extended periods of time. Such prolonged presence of antigen fosters the preferential expansion of high-affinity T cell

clones and contributes to the long-term presence of sizable frequencies of memory cells.

Much of the recent progress in understanding naive and memory T cells has been made possible by the identification of cell surface markers which reliably discriminate between them. Although a variety of molecules are differentially expressed by these subsets, the most useful and widely used are different forms of the CD45 molecule which differ due to differential RNA splicing. Immature or naive T cells may be identified by their expression of the high molecular weight isoform of the CD45 molecule known as CD45RA (or CD45R in older nomenclature). Mature or memory T cells express the low molecular weight isoform of CD45 known as CD45R0. Although CD45 isoforms are, in effect, the benchmark, other molecules have also been informative markers. In the mouse the cell surface glycoprotein Pgp-1 is differentially expressed; naive cells are Pgp-1 dull and memory cells are Pgp-1 bright. Murine studies have also employed the differential expression of CD45RB as a naive/memory discriminator. In human studies memory cells were noted to have enhanced expression of CD29 (the β chain of the VLA family of integrin molecules), CD58 (LFA-3) and CD26 (Tp103) which identify distinct but functionally related subsets. All of these molecules have been used as alternative markers of memory T cells by different research groups.

The conclusion that the T cell subsets can be distinguished by markers such as the CD45 isoforms is based on the following lines of investigation.

1. T cells from newborns are almost entirely of naive phenotype, and the percentage of T cells of memory phenotype increases progressively with aging. This fits the concept that the newborn has had minimal antigenic exposure, and that memory cells accumulate over time as a consequence of antigen exposure.
2. The term 'recall' response refers to immunologic responses of individuals who have been previously exposed to the specific antigen. For example, strong T cell proliferation to antigens such as tetanus toxoid or *Candida* are observed *in vitro* only with cells from individuals previously exposed to these antigens. Any putative marker of naive versus memory T cells should allow separation of T cells into one subset which mounts a strong recall response and another which fails to. The markers discussed in the preceding paragraph generally behave in this predicted manner.
3. Memory cells are believed to differentiate from naive cells *in vivo*. This expectation fits with the

in vitro findings that following activation naive cells generally acquire the memory phenotype characterized by the foregoing markers. This conversion has also been noted for single cells with clonal analysis.

The phenotypic definition of naive and memory T cell subsets with CD45 isoforms as described above is likely to be an oversimplification that will need to undergo further refinement as new data emerge.

Differential expression of molecules that define naive and memory T cells has not been useful in differentiating between memory and effector cells. An effector CD4⁺ T cell actively secretes cytokines in contrast to a memory CD4⁺ T cell which has to be stimulated with antigen to elicit cytokine production. The relationship between memory and effector T cells is not well-defined at present.

Concepts of differential migration are an important part of the foregoing description of naive and memory T cells. Some of these concepts derive from immunohistologic studies of the cells present in murine and human tissue. It is apparent that memory cells are the predominant ones present in most tissues including skin, intestinal mucosa and on the surfaces of lung mucosa. Further, kinetic studies of migration into sites of dermal inflammatory responses demonstrate selective migration of memory cells. These studies are complemented by studies in sheep which provide a particularly useful experimental model because of their well-developed lymphatic system. Sheep studies elegantly document transit of memory cells through tissue into afferent lymphatics and of naive cells through lymph nodes into efferent lymphatics. Presumably this pattern of recirculation optimizes encounters of the appropriate T cell with antigen.

There is experimental evidence to suggest that memory T cells are easier to activate than naive cells. This has been best illustrated by several groups using the proliferative response of human T cells to antibodies against the T cell receptor (TCR) complex. No biochemical mechanism to explain this has been identified and there are comparable amounts of TCR molecules on both subsets. It is plausible that the acquisition of memory by a T cell may share common biochemical features with memory acquisition in other cell systems. For example, in neural models there is evidence that the properties of protein kinase C, a key enzyme in cellular activation, are altered with memory acquisition. There is some evidence to suggest that the CD45 molecule itself has an important role in regulation of T cell activation as a consequence of its cytoplasmic portion which is a tyrosine phosphatase. One important explanation

for the enhanced triggering of memory T cells is their increased expression of adhesion molecules, as mentioned above, most of which are capable of also providing activation signals.

In the DTH scenario outlined above, CD4⁺ cells were the focus. It is apparent, however, that there is similar diversity among memory (as well as naive) CD8⁺ cells. There are memory cytotoxic T cells which, like the DTH cells, undergo clonal expansion and conversion of surface phenotype. Effector CD8⁺ cytotoxic T lymphocytes (CTLs) have spontaneous cytotoxic activity, whereas memory CTLs need restimulation with specific antigen to become active.

B cell memory

Antibody responses, like DTH responses, differ dramatically between naive individuals and individuals who have been primed by exposure to antigen. Induction of a primary antibody response requires a significant dose of antigen and gives rise largely to low-affinity antibody of the immunoglobulin M (IgM) isotype which appears typically at day 5. In contrast, the secondary response that results from re-exposure to that antigen appears sooner and is marked by a higher titer of mainly IgG antibody with higher affinity for antigen. The secondary response can be evoked with a lower antigen dose than that required for priming.

The differences between primary and secondary antibody responses reflect contributions both of helper T cells and of B cells. B cells, like T cells, can be classified into naive (or virgin) and memory (or primed) subsets based on whether they have undergone stimulation by antigen. For the sake of simplicity in this discussion, we start by assuming the simple model that when a naive B cell is stimulated by antigen, some of its progeny differentiate into plasma cells (which actively produce antibody) and the remainder of its progeny differentiate into memory cells. Many of the principles of B cell memory are similar to those outlined above with regard to T cells: clonal expansion, clonal selection, differentiation of surface phenotype and change in responsiveness to stimulatory signals.

Clonal expansion of B cells is conceptually similar to that with T cells. The frequency of B cells specific for any particular antigen is low and the proliferation which results from antigen stimulation amplifies the number of cells reactive with a given antigen. This increase in frequency of antigen-specific cells partially explains the faster kinetics and enhanced magnitude of a secondary antibody responses. Clonal selection also operates, and is probably even

more important for B cells than for T cells for two reasons:

1. The mechanism of clonal selection is an extremely efficient one. The surface immunoglobulin (sIg) on B cells competes for soluble antigen; the B cells whose sIg has the highest affinity will capture the available antigen and be triggered by it (together with other signals).
2. Unlike T cells, B cells undergo dramatic diversification of their receptor (Ig) by a process of random somatic mutation as they undergo clonal expansion. Therefore, as the response develops, clonal selection is essential for choosing for further expansion those B cells with the most avid Ig.

Memory B cells express an altered cell surface phenotype. The most characteristic feature is change in immunoglobulin isotype. Naive B cells express surface IgD, as well as IgM. After stimulation they lose their IgD; they also undergo isotype switching from IgM to IgG (and for some eventually IgE or IgA) when provided with appropriate help by T cells. Although many other changes in B cell phenotype have been noted, it has not been straightforward to distinguish those which accompany acute activation from those which consistently identify memory cells. Memory B cells also have a reduced number of Ig receptors which increases the stringency of the clonal selection by making it more likely that antigen in limiting amounts will only trigger cells with high-affinity receptors.

The site of memory B cell production appears to be the germinal center of the lymph follicle. Resting naive B cells are thought to be unable to enter lymph follicles but following initial activation their migration properties are altered so that late in the primary response they have that capacity. There, the B cell encounters antigen that is complexed to both antibody and complement on the surface of specialized APCs known as follicular dendritic cells. These cells, which have long complex cytoplasmic processes, are capable of interaction with several different lymphoid cells and antigen may be detected unmodified on their surface some 12 months after primary immunization. It seems that these cells can form a 'network' through which there is a continuous recirculation of migrating B cells. This arrangement allows for the continued encounter and stimulation of specific memory B cells with retained antigen over long periods which may be critical in maintaining immunity.

The foregoing discussion assumes that a single lineage of B cells differentiates into both plasma cells and memory cells; this bifurcation could be dictated

by differences in the lymphokine and cellular milieu that individual progeny encounter. An alternate possibility is favored by recent data. It proposes that there are two distinct lineages stimulated in the primary response: one lineage produces plasma cells in the primary response but not memory cells; the other generates memory cells which differentiate into plasma cells only during subsequent responses.

Synergism due to cooperation of different kinds of memory cells

The foregoing sections discuss memory T cells and memory B cells in isolation. In reality, immunologic responses in a primed individual involve cooperation of a variety of different kinds of memory cells. For example, memory helper T cells produce interleukin 2 (IL-2) which facilitates the response of memory cytotoxic T cells. Similarly, memory (primed) T cells provide help to memory B cells. Such cooperativity results in marked increases in efficiency of responses.

A special feature of T/B cooperativity relates to the capacity of B cells to act as APCs. This is of special significance when only small amounts of antigen are present; B cells are unique among APCs since their surface Ig enables them to concentrate antigen more than 1000 times as efficiently as is possible by simple pinocytosis. So one can envisage in a secondary immune response a memory B cell which expresses high-affinity antibody concentrating minimal amounts of antigen. A cognate interaction of high efficiency may then ensue with a memory T cell enhanced by its adhesiveness. This may then result in the prompt production of effector T cells and high-affinity antibody; production of the latter is augmented by the helper function of the memory T cell, notably the production of cytokines such as IL-4 that are potent in influencing B cell function.

Perspective and implications

A more profound understanding of the mechanisms of immune memory will provide the basis for more rational and effective strategies to manipulate the immune system to produce longstanding immunity against threatening pathogens. This is relevant not only to organisms to which there is no effective vaccine at present (notably malaria parasites and human immunodeficiency virus (HIV)) but also many organisms to which there are existing vaccines that warrant improvement in terms of efficacy and/or ease of administration. Derangements of the cellular and molecular processes that are the foundation of immune memory probably contribute to the pathogenesis of many disease states. This is clearly true for

allergic conditions and indeed may be valid for many other diseases which are presently categorized as being autoimmune in nature. Again, understanding of the mechanism of immune memory may lead to novel therapies for both prophylaxis and therapy of these and other related diseases.

MERCURY AND THE IMMUNE SYSTEM

Göran Sandberg, Lymphocyte Unit, Department of Neuroscience, Karolinska Institute, Stockholm, Sweden

Mercury is a compound without any known physiological action in the human organism. It is instead a member of a group of highly toxic metals and has effects on, for example, enzyme function and calcium ion channels at concentrations only slightly above those normally found in healthy subjects. Exposure to mercury occurs not only through environmental pollution but also deliberately, for example in various therapeutic preparations. Mercury is known to be particularly toxic for the kidneys and central nervous system and effects on the reproductive system have also been suggested. A carcinogenic effect may exist, judging from kidney tumour formation in methyl mercury-exposed male ICR mice and mercuric chloride-exposed male F344/N rats. Interesting effects of this metal on the immune system have been demonstrated. Mercury is allergenic, affects production of immunoglobulin and induces multispecific antibodies and autoimmune reactions. Mercuric chloride is a polyclonal activator of both B and T lymphocytes. A clear genetic influence on the immunological effects of mercury exists. This is of particular interest considering the suspected great individual differences in sensitivity to mercury in humans. That the polyclonal activation of T cells is genetically controlled is quite unique.

Exposure to mercury

To most people exposure to mercury occurs mainly through the consumption of fish from polluted lakes and mercury release from amalgam fillings. The

relative contributions of these mercury sources were evaluated to be in the same order of magnitude but depend, of course, on food preferences, living region and dental status. Certain categories are more heavily exposed to mercury, such as dental healthcare personnel and some industrial workers. High mercury concentrations were, for example, found in pituitary glands from dental staff. A correlation has been shown to exist between number of amalgam fillings and the plasma level of mercury. Amalgam fillings release mercury as vapor, which is then inhaled and absorbed, oxidized (ionized) and bound to cellular proteins. In fish, mercury is in the form of methyl mercury, formed by methylation by bacteria in polluted lakes. Methyl mercury can be biotransformed to inorganic mercury, and it was shown in Wistar rats that the spleen was of major importance for this action, presumably involving macrophages. People are also exposed to mercury through its use as a bactericidal agent and in dermatological and ophthalmic practice (antiseptic solutions, cosmetics, eye drops), nasal drops and thermometers. Mercury compounds are furthermore used as preservatives in preparations for parenteral use and have been used as antisyphilitic agents, diuretic agents, as purgatives and in antitussive therapy. Metallic mercury was used to treat some forms of ileus in the eighteenth century and was suspected to be still in use in folk medicine in some cultures even in modern times. It has also been used in pressure therapy of limbs in various conditions. During a

part of the twentieth century organic mercury compounds were used for treatment of seeds.

Mercury levels in humans

It is of interest to relate the concentrations of mercury occurring in humans to those affecting the immune system in experimental animal studies. Plasma levels of mercury detected in healthy humans is in the order of $1\text{--}10\text{ ng ml}^{-1}$. In contrast, whole blood mercury levels of persons living in a polluted region were reported to exceed $12\text{ }\mu\text{g ml}^{-1}$. Symptoms of mercury intoxication were already seen at a blood level of 20 ng ml^{-1} . Mercury intoxication occurring in patients after use of mercury-containing ointment was associated with plasma levels of $1\text{ }\mu\text{g ml}^{-1}$. Concentrations of less than $10\text{ }\mu\text{g ml}^{-1}$ were reported to be cytotoxic for human lymphocytes, methylmercuric chloride being considerably more toxic than mercuric chloride. In the acute phase after removal of amalgam fillings, plasma levels may increase substantially above normal, and later fall to lower than initially. It has been calculated that individuals with many amalgam restorations absorb as much as $10\text{ }\mu\text{g}$ mercury a day. *In vitro*, optimal mitogenic concentrations were reported to be $10\text{ }\mu\text{M}$, corresponding to $3\text{ }\mu\text{g ml}^{-1}$. For comparison, splenomegaly and increased serum immunoglobulin with antinuclear antibody formation was induced in SJL mice after treatment with repeated injections of 1.6 mg mercuric chloride. Thymic involution was induced in Wistar rats with injections of 1 mg mercuric chloride per kilogram body weight. In guinea pigs, local injection of $10\text{ }\mu\text{g}$ mercuric chloride caused reduced viability and inhibited proliferation of lymphocytes in the thymus. Less than 1 ng ml^{-1} methyl mercury causes calcium-mediated hyperpolarization of mouse (ddY strain) thymocytes.

Effects of mercury on the immune system

Little is known about the principal mechanism by which mercury affects the immune system. An effect on the selection mechanisms in the thymus has been suggested, allowing potentially autoreactive cells to escape into the periphery. A direct mitogenic action on lymphocytes seems to be well established and could result from the chemical effects of this heavy metal on some cell membrane components, such as calcium channels, or direct action on nuclear proteins. Other possible mechanisms would be increased expression of major histocompatibility complex (MHC) class II molecules on cell surfaces, with consequences for antigen presentation, or alterations

of surface antigens into immunogenic forms. A well-documented toxic action might cause release of cellular proteins inducing autoimmune reactions.

Mercury has an affinity for SH-groups and may interact with enzymes and other cellular proteins. In several species (such as humans, guinea pigs, rats, mice and rabbits) *in vitro* culture of lymphocytes (from blood, thymus, lymph nodes or spleen) in the presence of mercuric chloride results in blast transformation and increased mitotic activity. At least in human and murine lymphocytes increased DNA synthesis and mitotic activity is found after treatment with concentrations of mercury compounds close to toxic levels. In BALB/c mice the mitogenic effect seemed to be macrophage dependent. In humans, the responsiveness was reported to increase with age. In guinea pigs, thymocytes from newborn animals were the most easily stimulated by mercury, whereas in older animals spleen cells responded better. In BN strain rats, mercury induces proliferation of both T helper and B lymphocytes in peripheral lymphoid organs, and over-production of different immunoglobulin (Ig) isotypes, preferentially IgE. An early thymic atrophy and increased lymph node weight are also seen.

As shown in BN rat spleen cells, the effects of mercuric chloride are associated with increased production of interleukin 2 (IL-2). In accordance with *in vitro* results, individuals occupationally exposed to mercury have an increased absolute number of T lymphocytes which correlated with the time of exposure. Of particular interest are the different effects of mercury on T helper cells, T suppressor cells and B cells, obviously of importance in understanding the imbalance of the immune system after such treatment. In BN rats, autoreactive T helper cells were initially induced by mercury, and later the appearance of T suppressor cells was demonstrated. These latter cells may be responsible for the self-limiting nature of this autoimmune response. Mercuric chloride is responsible for inhibition of suppressor T cells in PVG/c rats, which develop immune complex glomerulonephritis and antinuclear antibodies. In contrast, in LEW (Lewis) rats, MRC OX-8⁺ cells (suppressor cells) are increased and associated with immunosuppression. These suppressor cells are possibly responsible for mercury-mediated protection against experimental allergic encephalomyelitis in these animals. It seems that in nonresponding strains there is no proliferative response among T helper cells.

In some studies, very low levels of methylmercuric chloride or mercuric chloride inhibit RNA and DNA synthesis, mitogen responses and immunoglobulin production. They furthermore cause downregulation

of some receptors, reduced viability and signs of apoptosis. It has been reported that different immunoglobulin isotypes are differentially affected, IgG1 being the most easily inhibited. Methylmercuric chloride and, to a lesser extent, mercuric chloride also may inhibit activation of mouse (BALB/c and C57BL) lymphocytes, both by mitogen and by MLC stimulation. In guinea pigs, *in vivo* experiments with mercuric chloride resulted in inhibition of thymocyte proliferation (as in Wistar rats) but at the same time decreased negative selection, possibly resulting in formation of an increased fraction of potentially autoimmune cells.

The mechanism by which mercury causes these effects is not known. According to studies with mouse (strain ddY) lymphocytes, methyl mercury increases intracellular Ca^{2+} . It was also shown to be incorporated into lymphocyte nuclei and to increase phosphorylation of nuclear proteins. Some evidence indicates that interaction with immune function is due to inactivation of glutathione. Antigen-specific sensitization to mercury can occur in both humans and experimental animals. BALB/c mice are readily sensitized to mercury by epicutaneous exposure. Certain inbred guinea pig strains can also be sensitized to mercury.

Autoimmune renal disease

One of the more interesting effects of mercury is the induction of autoimmune renal disease. In rabbits, and certain susceptible rat (BN, Wistar, MAXX, PVG and other) and mouse (A.SW, SJL, BALB/c and C3H.NB) strains, mercury may induce an autoimmune glomerulonephritis. In humans, the glomerular dysfunction caused by mercury has also been suggested to have an autoimmune component. In susceptible laboratory strains the disease is associated with T lymphocyte-dependent polyclonal B cell activation, resulting in the formation of antibodies against a broad range of antigens which can include glomerular basement membrane (GBM), immunoglobulins, DNA, myeloperoxidase, sheep erythrocytes, TNP, laminin, type IV collagen, entactin and nucleolar components. Both granular and linear IgG deposits along the glomerular basement membrane and detachment of endothelial cells are seen, as well as proteinuria. In the susceptible rat strain BN it is a self-limiting autoimmune response, and the animals are rendered resistant to rechallenge with mercuric chloride. CD8^+ T cells were of importance in maintaining resistance to mercuric chloride. Immunoregulatory T lymphocytes bearing the marker RT6 have been suggested to be of significance in the recovery process, as their number in peripheral lymphoid

organs inversely correlates with the autoimmune response. They were not affected in a similar way in the nonresponding LEW rats. All manifestations of mercuric chloride-induced nephritis in BN rats could be prevented by treatment with cyclosporine. Mercury also induces the formation of immune complexes which cause a mesangial immune complex glomerulonephritis and immune complex deposition in the vessel walls of the spleen and liver. In H2^s strains of mice (such as A.SW and SJL) mercury causes formation of autoantibodies against the highly conserved nucleolar protein fibrillarin. Interestingly, autoantibodies against this antigen are found in patients with scleroderma.

Genetic influence

An interesting aspect of mercury is the clear strain-dependence of its effect on the immune system. For instance, increased immunoglobulin levels are found upon mercury administration to A.SW mice, to some extent in C57BL/6 mice, but not at all in DBA/2 mice, and this difference between strains is correlated to their susceptibility to autoimmunity after exposure to mercury. Another mouse strain susceptible to induction of autoimmunity by mercury is SJL mice, whereas strain B6 is resistant. Proliferative enlargement of draining lymph nodes due to mercuric chloride was seen in most mouse strains, however DBA/2 and C3H nu/nu mice were totally unresponsive. Stimulation of DNA synthesis occurs in spleen cells of both A.SW and BALB/c mice, but not in DBA/2 mice. Antinucleolar antibodies can be induced by mercuric chloride in SJL, B10.S and Swiss ICR mice but not in A/J male mice. The genetic control of mercury responsiveness is thought to be multifactorial, involving both MHC and non-MHC genes. Formation of antinuclear and antinucleolar autoantibodies in mice is linked to H2. A.SW, SJL and B10.S (H2^s) strains are responders. Expression of H2 I-E may have a suppressive effect. The susceptibility in SJL mice to form antinucleolar antibodies resided in the H2 I-A locus and was codominantly inherited in a cross with resistant mice carrying the H2^b and H2^d haplotypes. The development of autoantibodies to chromatin and histones could not be mapped to the H2 complex. Differences between strains of mice in the response to mercury may also depend on in which form mercury is administered. For instance, strain differences in the popliteal lymph node response to mercuric chloride were not paralleled by similar differences in response to methylmercuric chloride. According to the isotype pattern, the immunoglobulin response of BALB/c, but not SJL, mice is mainly T cell dependent. A low response in

C57BL/6J mice could be increased by using Freund's complete adjuvant.

In rats, the BN and MAXX strains are susceptible to induction of autoantibodies to GBM and autoimmune renal disease by mercury, whereas the LEW and Marshall 520 (M520) rats are relatively resistant. This difference is paralleled by a difference in serum IgE response, as it is in mice, and a difference in lymph node response, in that lymphadenopathy is seen only in BN rats. Thus, whereas mercury causes autoimmunity of BN rats, it instead causes immunosuppression in LEW rats, with increased numbers of suppressor cells and inhibition of local graft-versus-host reactions. Furthermore, mercuric chloride decreases the appearance of splenic interferon γ (IFN γ)-producing cells in BN rats, but not in LEW rats. Different strains of rats also respond differently to mercury as regards phagocytosis or release of hydrogen peroxide from granulocytes and macrophages. In humans, an unusual nephritis associated with GBM autoantibodies exists and is HLA-DR associated. As in mercury-treated BN rats, the production of autoantibodies is spontaneously self-limiting. This condition is therefore an interesting parallel to the mercury-induced renal disease in other species.

As for guinea pigs, contact hypersensitivity to mercury can be induced in strain XIII of guinea pigs but not in strain II.

Mercury-induced, immune system-related disease in humans

Allergic contact dermatitis is a well-established complication of mercury exposure. It may result from handling of metallic mercury and/or topical administration of mercury-containing agents. Allergic contact dermatitis has also been described in persons exposed to mercury-containing antiseptic solutions, cosmetics or eye drops, or following inhalation of mercury vapour. Allergic contact dermatitis to mercury appears to be one of several causes of the so-called baboon syndrome. Low amounts of mercuric chloride were shown to induce certain morphological changes in skin, such as glycogen deposition, appearance of lysosome-like bodies and electron-dense material in cells of the epidermis. In humans, mercuric chloride is a strong sensitizer but also a skin irritant, reducing its use in dermatological testing procedures. Oral lichen planus has been suggested to mirror existence of mercury-specific lymphocytes, as

a high proliferative reactivity in lymphocytes to mercury was noted in such patients, and as removal of amalgam was followed by disappearance of mucosal lesions. A reduced ability of granulocytes to kill ingested microorganisms was noted in workers of a mercury industry. Interference with myeloperoxidase activity and formation of mercury-NADPH complexes were suggested. In addition, the chemotactic migration of these cells was reduced.

Although a toxic influence of mercury on the human kidney is well known, the evidence for a possible immunological damage to kidney function remains weaker. An interesting observation in mice is upregulation of Ly-6 (the murine equivalent of human CD59), a possible target molecule in allogeneic responses, by mercuric chloride. Furthermore, there is extensive cross-reaction between BN rat and human GBM antigens. It has been suggested, therefore, that mercury may also induce autoimmune glomerulonephritis in humans. Both subnormal levels and increased levels of immunoglobulins and some other serum proteins have been reported in workers exposed to mercury. There have also been reports of immediate-type hypersensitivity reactions (urticaria, anaphylaxis, asthma) linked to mercury.

MHC DISEASE ASSOCIATIONS

Henry Erlich and **Raymond Apple**, Department of Human Genetics, Roche Molecular Systems, California, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The association of a disease with a genetic marker means that the frequency of a given allele at a specific locus is either increased (positive association) or decreased (negative association) among patients relative to controls. In case-control studies, a positive association indicates that the gene in question confers an increased susceptibility to the disease or is in linkage disequilibrium with a nearby allele that does. Similarly, a negatively associated gene is thought to confer protection or to be in linkage disequilibrium with another gene that is causally involved in the disease process. The relative strength of observed disease associations can be estimated by a variety of statistical measures (see below). In humans, a large number of different diseases are associated with specific alleles of loci in the HLA region (Table 1).

The human major histocompatibility complex (MHC), known as the HLA region, is located on the short arm of chromosome 6 (Figure 1) and encodes two distinct classes of highly polymorphic cell surface molecules (termed class I and class II antigens) that present peptide antigens to T lymphocytes, initiating both cellular and humoral immune responses. Over the past 30 years, a variety of diseases have been associated with alleles at the HLA loci, defined initially by serologic typing as HLA antigens. The

frequency of a specific HLA antigen (e.g. HLA-B27) can be greatly increased among patients with a specific disease (e.g. ankylosing spondylitis), an observation with important implications for differential diagnosis, identification of disease susceptibility and prognosis. The observed HLA disease associations can reflect, in principle, either some aspect of the HLA class I or class II molecules' function in the immune system or simply that the HLA loci are closely linked to and in linkage disequilibrium with other disease-conferring loci. Different HLA-associated diseases can be explained by either one or the other of these basic models (see below).

Most of the diseases that show significant HLA associations are autoimmune or inflammatory disorders; in some cases, the observed HLA association was critical in suggesting the autoimmune nature of the disease, as in the distinction between type I diabetes (insulin-dependent diabetes mellitus or IDDM), a disease involving the autoimmune attack of the pancreatic islet β cells, and type II diabetes (non-insulin-dependent diabetes mellitus or NIDDM), a metabolic disease. Some autoimmune diseases, such as Reiter's syndrome are elicited in individuals with a predisposing HLA type as a consequence of bacterial infection. Several cancers and several infectious

diseases have also been associated with specific HLA types, perhaps reflecting the role of the immune system in responding to the tumor or to the pathogen. In addition, some diseases like narcolepsy, a sleep disorder of unknown etiology and with no obvious connection to the immune system, show a strong HLA association.

The initial reports of HLA disease associations all relied on the serologic definition of class I and class II antigens, and to a lesser extent, the cellular definition of HLA class II antigens by the mixed lymphocyte reaction was also used. More recently, polymorphism at the HLA loci has been analyzed at the nucleotide sequence level, revealing a wealth of allelic diversity, and simple and rapid polymerase chain reaction (PCR)-based typing methods have been applied to studies of HLA disease associations. The capacity of PCR-based typing to distinguish alleles relative to serology has resulted in a much more precise understanding of disease associations; there are about 15 serological DR specificities but >150 DRB1 DNA sequence-defined alleles. Because DNA typing can reveal where and how alleles differ, the application of these methods has provided insight into the contribution of individual polymorphic amino acid residues to disease susceptibility. For example, the DR4 specificity can be encoded by any of 22 DRB1 alleles; some DR4-associated diseases (e.g. IDDM, rheumatoid arthritis (RA)) are positively associated with specific DR4 alleles, and negatively associated with others. The negatively and positively associated alleles can differ by as little as a single codon.

The HLA loci

The HLA loci on the short arm of human chromosome 6 (Figure 1) encode two distinct classes of highly polymorphic cell surface molecules that bind and present processed antigens in the form of peptides to T lymphocytes; recognition by the T cell of

the HLA-peptide complex, along with a costimulatory signal results in T cell activation. The class I molecules, HLA-A, -B and -C, are found on most nucleated cells. They are cell surface glycoproteins that bind and present peptides derived primarily from endogenously synthesized proteins (e.g. viral and tumor peptides) to CD8⁺ T cells. These heterodimers consist of an HLA-encoded α chain associated with the non-MHC-encoded monomorphic polypeptide, β_2 -microglobulin. These loci are highly polymorphic; the numbers of alleles at the HLA-A, -B and -C loci are shown in Table 2.

The class II molecules are encoded in the HLA-D region (Figure 1). These cell surface glycoproteins consist of HLA-encoded α and β chains associated as heterodimers on the cell surface of antigen-presenting cells such as B cells and macrophages. Class II molecules serve as receptors for processed peptides; however, these peptides are derived predominantly from membrane and extracellular proteins (e.g. bacterial peptides) and are presented to CD4⁺T cells. The HLA-D region contains several class II genes and has three subregions: HLA-DR, -DQ and -DP. Both the HLA-DQ and -DP regions

Table 2 Allelic diversity at the HLA class I and class II loci

Locus	No. of alleles
HLA-A	83
HLA-B	185
HLA-C	42
DRA1	2
DRB1	184
DRB3	11
DRB4	8
DRB5	12
DQA1	18
DQB1	31
DPA1	10
DPB1	77

The number of alleles listed here includes silent variants and is based on the 1996 WHO Nomenclature Report.

contain one functional gene for each of their α and β chains. The HLA-DR subregion contains one functional gene for the α chain; the number of functional genes for the β chain varies from one to two. All individuals express a DRB1-encoded polymorphic polypeptide that is found on the cell surface in association with the DRA-encoded polypeptide. The other functional class II DRB genes, DRB3, DRB4 and DRB5 encode polypeptides which are found on the cell surface in association with a DRA-encoded polypeptide but at a lower level and only in certain class II haplotypes. In general, the DRB3 locus is found on haplotypes where DRB1 is *03, *11, *12, *13 or *14; the DRB4 locus is found on haplotypes where DRB1 is *04, *07, *09 and the DRB5 locus is found on haplotypes where DRB1 is *02 (either *15 or *16).

With the exception of the DRA and the DPA1 loci, the genes encoding the functional class II molecules are highly polymorphic (see Table 2). Analysis of the HLA class II structure has shown that these polymorphic amino acid residues line the peptide-binding cleft and interact directly with the peptide and/or the T receptor. The extensive polymorphism at both the class I and II loci and its localization to the peptide-binding groove have led to the notion that HLA polymorphism is maintained in the population because different allelic products have the capacity to bind different peptides; consequently, the more alleles an individual or a population has, the better it is able to cope with a variety of infectious pathogens.

Allelic sequence diversity

The allelic sequence diversity of the HLA class I and class II loci is the highest among mammalian coding sequence polymorphisms, with the number of alleles at some loci approaching 200 as of 1996 (see Table 2). The functional significance of this extensive polymorphism as well as the genetic mechanisms and the evolutionary forces that have generated and maintained this sequence diversity are the subject of many immunological and genetic investigations. For the HLA class II genes, the loci encoding the α and β chains of the DR, the DQ and the DP antigens, virtually all of the polymorphism is localized to the second exon. This exon encodes the α -helical 'walls' and the β -pleated sheet 'floor' of the peptide-binding groove formed by the $\alpha\beta$ heterodimer. Among the α chain loci (e.g. DRA), only the DQA1 locus, with over 15 alleles, shows extensive polymorphism. The β chain loci, however, are highly polymorphic. Population surveys in a variety of human populations have identified over 77 alleles at the DPB1 locus and over 184 at the DRB1 locus. A small number of these alleles are identical in amino acid sequence and differ

only at the nucleotide level through silent substitutions. The other DRB loci (i.e. DRB3) show a relatively modest number of alleles (Table 2) although some of the alleles at DRB3 differ at many different sites.

In contrast, the HLA class I HLA-A, -B and -C antigens contain polymorphic $\alpha 1$ and $\alpha 2$ protein domains that comprise the peptide-binding groove encoded within a single heavy chain. The $\alpha 1$ and $\alpha 2$ domains are encoded in the second and third exons respectively. Like the class II loci, the class I loci are highly polymorphic: population studies have revealed 80 alleles at the HLA-A locus, 175 alleles at the HLA-B locus, and 38 alleles at the HLA-C locus. In general, a given population contains only a subset of the class I or class II alleles that have been identified worldwide and different populations have different allele frequency distributions.

Nomenclature

In the WHO nomenclature for HLA alleles, the locus (e.g. DRB1) is followed by an asterisk (*) and by two digits that identify the allele group (e.g. DRB1*04 which, in this case, corresponds to the serologic DR4 type) and two digits that identify the allele or DR4 subtype (e.g. DRB1*0401, DRB1*0402, etc.). An additional digit is used to designate silent variants, that is, different nucleotide sequences that encode the same amino acid sequence (e.g. DRB1*08041 and *08042). For some loci, all the alleles within a single allele group designation (e.g. HLA-B*15) do not necessarily encode the same serologic type.

HLA typing

Serologic and cellular methods

Historically, HLA typing has been performed by using a combination of the serologic microcytotoxicity and, in special cases, mixed lymphocyte reaction (MLR) assays. In the microcytotoxicity assay, which can be used to type both class I and II antigens, an antiserum (or monoclonal antibody) is mixed with live lymphocytes and allowed to bind to the cell surface molecules. Specific binding is then detected with the addition of complement which lyses the cells and allows the uptake of a dye. The microcytotoxicity assay requires viable cells and uses antisera obtained primarily from individuals who have been sensitized to HLA differences such as multiparous women (women who have had multiple pregnancies) or individuals who have received multiple transfusions. Consequently, these reagents are limiting in quantity and difficult to standardize. Although, as noted above, >150 DRB1 alleles (different amino acid

sequences) have been identified, serologic reagents can distinguish only 15 different groups of DR molecules encoded by these alleles.

DNA-based techniques

Over the last decade, molecular genetic techniques have been used to isolate the genes encoding the HLA class I and class II molecules and to characterize their genomic organization. The initial approach to HLA typing at the DNA level involved the restriction fragment length polymorphism (RFLP) method; provided that several restriction enzymes were used, this technique could often subdivide HLA class II serotypes. However, RFLP typing failed to distinguish much of the HLA class II sequence polymorphism.

The development of the PCR in the mid-1980s greatly facilitated the analysis of sequence polymorphism at both the class I and II loci. By generating billions of copies of the target sequence, this technique enabled the use of simple, nonradioactive methods to analyze sequence information. Based on the available database of class II allelic sequence diversity, a variety of relatively simple and rapid PCR-based methods has been developed to carry out HLA class II typing at the DNA level. The first approaches utilized labeled sequence-specific oligonucleotide (SSO) probes to hybridize to PCR products amplified from the sample and immobilized on a nylon or nitrocellulose filter, the 'dot blot' method. Under appropriate hybridization and wash conditions, these SSO probes would bind only to the complementary sequence in the amplified DNA and were able to distinguish single nucleotide differences. Given enough primers and probes, the SSO method is, in principle, capable of distinguishing all of the alleles at a given HLA locus. It has now been applied to typing all of the class II loci and, more recently, to the class I loci.

Another PCR-based approach, based on the specificity of primer extension rather than probe hybridization, has also been applied to HLA typing. This method is known variously as allele-specific amplification (ASA), sequence-specific priming (SSP), and the amplification refractory mutation system (ARMS). Here, a specific primer pair is designed for each polymorphic sequence motif or pair of motifs and the presence of the targeted polymorphic sequence in a sample is detected as a positive PCR, typically identified as a band on a gel. If the PCR is negative, the sample is assumed to lack one or both of the specific motifs. Allele-specific amplification can be used in conjunction with SSO probe typing for high-resolution typing. Other PCR-based methods such as PCR-RFLP, PCR-SSCP (single-

strand conformation polymorphism), and PCR-DHA (directed heteroduplex analysis), have also been developed but are not widely used.

Recently, a new approach to SSO probe analysis of HLA polymorphism has been developed that facilitates DNA-based HLA typing. The conventional dot blot involved an immobilized PCR product that is hybridized to each of many labeled SSO probes. The 'reverse blot' (or immobilized probe) method is based on the hybridization of PCR product, labeled with biotinylated primers during the amplification, to an array of immobilized probes on a membrane. This procedure requires only a single PCR and a single hybridization reaction to obtain information from the entire SSO probe panel; all of the probe reactivity information is contained on a single membrane, making it amenable to automated data interpretation.

Possible explanations of MHC disease association

Although most diseases associated with HLA are autoimmune or inflammatory in nature, HLA antigens may also influence the progress of disease caused by certain infectious organisms. In addition to autoimmune disorders, such as IDDM and multiple sclerosis (MS), diseases shown to have an HLA association include several cancers such as cervical carcinoma (CC), Hodgkin's disease (HD), and nasopharyngeal carcinoma (NPC). These cancers all have a viral association; CC and the precancerous cervical lesions are caused by human papillomavirus (HPV) while HD and NPC are both associated with Epstein-Barr virus (EBV). Relatively few studies of infectious diseases have revealed HLA associations, although specific HLA-B and HLA-DRB1 alleles have been associated with resistance to severe malaria in African populations, and other HLA alleles have been associated with leprosy, tuberculosis and hepatitis. In general, the fundamental mechanisms underlying the HLA disease associations are not fully understood.

Some diseases are associated with specific HLA alleles because these alleles are in linkage disequilibrium with disease-causing mutations or polymorphic variants at a nearby locus. For some autoimmune diseases, immune-related MHC genes other than the HLA class I or class II loci appear to be involved. For systemic lupus erythematosus (SLE), complement deficiencies appear to play a role in pathogenesis; the C4A null allele in linkage disequilibrium with DR3 may account for the observed DR3 association with SLE in Caucasians. Several HLA-associated diseases that are not autoimmune disorders, such as congeni-

tal adrenal hyperplasia (CAH) or hereditary hemochromatosis (HH) are now known to be caused by mutations in linked non-HLA loci. CAH is the result of mutations in the gene for 21-hydroxylase (CYP21B) between HLA-B and DRB1, while HH is due to a mutation in a newly discovered locus (HFE) of unknown function telomeric of HLA-A that is apparently related to the HLA class I family. The common HH mutation (Cys282Tyr) is in strong linkage disequilibrium with HLA-A3.

For most of the HLA-associated diseases, however, the observed association is likely to be attributed to variation in the amino acid sequence of the HLA molecules themselves. The model that an associated HLA allele is directly involved in disease pathogenesis rather than serving as a linked marker is supported by the example of celiac disease, an inflammatory disorder, resulting in malabsorption in the small intestinal mucosa, precipitated by the ingestion of gluten. The DRB1*0301-DQA1*0501-DQB1*0201 haplotype is associated with celiac disease in all populations studied. In some populations, heterozygotes for the haplotypes DRB1*0701-DQA1*0201-DQB1*0201 and DRB1*1101-DQA1*0501-DQB1*0301 are also associated with celiac disease. The observed disease association with DR7/11 heterozygotes suggests a model in which *trans*-complementation of the α chain encoded by DQA1*0501 and the β chain encoded by DQB1*0201 form the same DQ heterodimer as that encoded *in cis* on the DR3 haplotype. This model of *trans*-complementation is consistent with the DQ molecule itself being responsible for the pattern of HLA association with celiac disease rather than the contribution of a linked non-HLA gene.

Peptide binding

The chief function of the HLA class I and class II molecules is to bind antigenic peptides, and present them to CD8⁺ and CD4⁺ T cells, respectively. The susceptibility to some autoimmune diseases conferred by certain HLA alleles could simply reflect the ability of a particular HLA molecule to bind and present a specific peptide derived from an autoantigen. Supporting evidence for this model is found in many human autoimmune diseases, as well as the corresponding animal models.

Multiple sclerosis (MS) is an inflammatory demyelinating autoimmune disease of the central nervous system in which myelin proteins have been implicated as autoantigens recognized by pathogenic autoreactive T cells. In certain strains of mice, immunization with myelin basic protein (MBP), induces experimental allergic encephalomyelitis (EAE), which serves as a model for the T cell autoimmunity

seen in MS. T cells recognize only a limited number of possible epitopes on an antigen, which are termed immunodominant. Studies of MBP T cell epitopes in EAE have demonstrated that susceptible mouse strains recognize an immunodominant epitope; in the EAE-susceptible I-A^u mouse strain (B10.PL), the N-terminal MBP Ac1-11 is immunodominant, whereas in the EAE-susceptible I-A^s mouse strain (SJL), MBP 81-100 is immunodominant. The I-A molecules, the homolog of the human HLA-DQ, of these two mice strains differ in the amino acid sequences that comprise the peptide-binding groove. It has been demonstrated that MBP Ac1-11 binds to I-A^u molecules, but not to I-A^s molecules, and that immunization of I-A^u mice with MBP Ac1-11 can induce EAE. In humans, the HLA region has been implicated as a susceptibility locus for MS, and MS patients have an increased frequency of the DRB1*1501-DQB1*0602 haplotype relative to controls. Studies of the role of human MBP (hMBP) as an autoantigen in MS, and of the epitope specificity of hMBP-reactive T cells have demonstrated that some hMBP peptides bind with highest affinity to molecules encoded by those HLA class II alleles found to be increased in MS patients (DRB1*1501). These studies have implicated hMBP 84-103 as a possible immunodominant determinant.

In rheumatoid arthritis (RA), up to 80% of patients express DR4. The DR4 serologic specificity is present on 22 different DRB1 molecules; however almost all DR4-RA patients possess either the DRB1*0401 (Dw4), DRB1*0404 (Dw14), or DRB1*0405 (Dw15) alleles of the DR4 serogroup. All of these alleles differ from each other in amino acid residues that lie within the peptide-binding groove. Recent evidence suggests that molecules encoded by the genetically susceptible DR4 alleles bind different peptides in their peptide-binding grooves than those encoded by nonsusceptible alleles (such as DRB1*0402), although the nature of the autoantigen in RA is still unknown. Similarly, in IDDM, peptide elution studies have also added indirect support that HLA-DQ and HLA-DR polymorphisms (and I-A in the NOD mouse model of IDDM) influence susceptibility to IDDM by affecting the peptides presented to T cells by these class II molecules.

Another HLA-associated disease consistent with a peptide-binding model is the autoimmune dermatologic disease pemphigus vulgaris (PV). PV is associated with the DR4 subtype, DRB1*0402-DQB1*0302 as well as with the DRB1*1401-DQB1*0503 haplotype. Peptides derived from the putative autoantigen, Pe V antigen complex, have been shown to

bind to the DRB1*0402-encoded DR molecule but not to other DR4 molecules.

T cell subsets (T_H1/T_H2)

Although selective autoantigen-peptide binding and presentation can readily explain many HLA-disease associations for susceptible alleles in autoimmunity, protective HLA allele associations in autoimmunity require different models. In studies of IDDM among Caucasians, DRB1*1501-DQB1*0602 appears to be strongly protective; studies of IDDM in other ethnic groups have demonstrated additional protective alleles or haplotypes – such as DRB1*1402-DQB1*0301 in Mexican-Americans. Siblings of diabetics carrying a protective DRB1*1501-DQB1*0602 haplotype can be shown to produce high titers of autoantibodies to islet cell antigens such as glutamic acid decarboxylase (GAD-65), but do not develop diabetes, indicating that disease protection does not necessarily mean lack of an immune response to autoantigens.

Class II-restricted CD4⁺ T helper cells differentiate into two distinct populations following antigenic stimulation: T_H1 and T_H2 cells. These distinct subpopulations each produce its own set of cytokines and mediate separate effector functions. T_H1 cells produce interleukin 2 (IL-2), IL-12, tumor necrosis factor β (TNF β) and interferon γ (IFN γ), which are important in cell-mediated immunity; T_H2 cells produce IL-4, IL-5 and IL-10, stimulating antibody formation and possibly suppressing cell-mediated immunity. Preferential stimulation of one T cell subset over the other appears to play a role in autoimmunity, although the mechanisms that determine whether an immune response will be predominantly T_H1 or T_H2 are not yet understood. In the mouse EAE model, studies have shown that EAE is induced by T_H1 cells, and that T_H2 cells can prevent induction of disease, as well as abrogate established disease. Cytokines mediating inflammatory responses have been demonstrated in RA and the islet cell damage in IDDM appears to be mediated by T_H1 cells.

Therefore, while susceptible and resistant HLA alleles may encode molecules that present peptides from the same autoantigen, they most likely bind different subsets of peptides and stimulate different subsets of T cells. It has been demonstrated that altered peptide ligands can control CD4⁺ T cell differentiation. Peptide/class II complexes that interact strongly with a T cell receptor favor the generation of T_H1 cells, whereas complexes that bind weakly favor the priming of T_H2 cells. An additional model for a class II protective role has been proposed, suggesting that susceptible and protective class II alleles compete for peptides during antigen processing of

autoantigens, resulting in reduced levels of susceptible class II/autoantigen complexes for T cell activation.

T cell repertoire

In addition to their role in antigen presentation, class I and class II molecules also function to shape the developing T cell repertoire in the neonate. Although developing thymocytes in the fetal thymus are positively selected to react with peptides in the context of self-MHC, thymocytes that react strongly with self-MHC are clonally eliminated. In the mouse, entire subsets of T cells expressing certain T cell receptor (TCR) V_β genes (such as $V_\beta14$) are clonally eliminated in mice expressing an endogenous mouse mammary tumor virus and an I-E molecule, the homolog of the human HLA-DR. In this manner, the development of autoimmune diseases could be negatively or positively influenced through HLA allelic polymorphism by eliminating certain V_β expressing T cells from the periphery (termed a 'hole' in the T cell repertoire), as well as by selecting the repertoire of T cells available for antigen reactivity.

The removal from the periphery of entire subsets of V_β -expressing T cells has not been demonstrated in humans as it has been in mice. However, both mice and man have polymorphic T cell receptor V genes, with some haplotypes carrying insertion/deletion polymorphisms among the T cell V_β genes. While studies have demonstrated that these polymorphisms affect the resulting peripheral T cell repertoire, no study has shown convincing evidence that either peripheral T cell V_β gene use, or germline V_β polymorphism play a major role in human autoimmune disease.

Molecular mimicry

The sharing of antigenic epitopes at either the B cell or T cell level between a host and a pathogen has been termed 'molecular mimicry'. Originally, this was limited to discussions of a region of amino acids encoded within a pathogen with some degree of homology to either a class I or class II structural polymorphism, but now includes any similarity between pathogens and self antigens. In this model, the sharing of identical amino acid sequences present in a host class I or class II molecules or other self antigens with, for example, a viral pathogen could result in a lack of response or 'tolerance' to these viral epitopes, leading to an altered immune response to the virus. Alternatively, the initiation of an immune response to this virus might lead to response to the autoantigenic target within the host, leading to an attack of those tissues expressing the self antigen and the HLA product.

Some examples of molecular mimicry have been described. Molecular mimicry between HLA-B27 and two molecules in *Klebsiella* sp. – nitrogenase and pullulanase D – has been reported, and elevated immune responses to *Klebsiella* sp. have been demonstrated in patients with ankylosing spondylitis. Similarly, the haemolysis molecule encoded in *Proteus* sp. has some homology to DR1 and DR4 molecules, and an elevated response to *Proteus* sp. has been described in RA patients. Whether these autoimmune diseases are actually caused by these immune responses remains to be determined.

Myelin basic protein (MBP) shares amino acid sequence motifs with a number of pathogens, including measles, hepatitis B, influenza virus, and adenovirus. A number of these pathogens have been shown to stimulate MBP-reactive T cell clones from MS patients. These studies have indicated that sequence similarity may be necessary only at a few critical amino acids comprising a T cell epitope. In animal models, conservation of only four of 11 amino acid residues was sufficient to induce EAE following immunization. These experiments demonstrate that tolerance to a self antigen such as myelin could be broken by an immune response to a microbe.

Regulation

Another proposed mechanism for HLA disease associations suggests that it is the genetic variation in regulatory regions affecting gene expression, such as promoter sequences, rather than coding sequence polymorphism that is responsible for the observed pattern of associations. This model postulates that differences in the level of cell surface expression of HLA molecules may have a major effect on their ability to present specific peptide antigens; these differences could, in principle, be manifested at the level of constitutive expression, expression in specific tissues, such as the thymus, or induced expression in response to signals such as interferon γ . In order to account for the observed disease associations, this hypothesis requires linkage disequilibrium between the coding sequence variation identified by serological typing or DNA-based typing and regulatory sequence polymorphism. At present, no compelling evidence for the involvement of regulatory mechanisms in HLA disease associations has been reported.

In general, the potential mechanisms postulated to underly HLA disease associations that are discussed above need not be mutually exclusive.

Population genetics, linkage disequilibrium and linkage

For some diseases, a given HLA allele may be strongly associated with disease in some populations but not in others. This apparent discrepancy may reflect the different distribution of alleles in different populations. For example, DR3 (DRB1*0301-DQB1*0201) is associated with IDDM in most populations but not in Japan, where DR3 is extremely rare. Another possible explanation for discrepancies in the observed disease associations in different populations are differences in the patterns of linkage disequilibrium (see below). For example, DPB1*0401 is increased among IDDM patients in China but not in other populations. This association can be attributed to strong linkage disequilibrium with DR3 in Chinese populations; these alleles at DRB1 and DPB1 are not in linkage disequilibrium in other populations. For diseases involving an infectious pathogen, differences in HLA associations in different populations could, in principle, be attributed to genetic differences in the pathogen. In the Gambia, DRB1*1302 appears to confer resistance to severe malaria whereas in Kenya, DRB1*0101 but not DRB1*1302 appears to be protective. The most common strain of *Plasmodium falciparum* responsible for malaria in these two African countries is different; this difference may account for the difference in the observed HLA associations.

In some cases, the differing incidences of a given disease in different populations or countries can be attributed, at least in part, to the differences in the frequency of the relevant HLA alleles. Pemphigus vulgaris, for example, is frequent among Ashkenazi Jewish populations; one explanation may be that the disease-associated DR4 allele, DRB1*0402, is the most common DR4 allele in this population but is an infrequent DR4 subtype in other populations. For some HLA-associated diseases, several different alleles may confer susceptibility to varying extents; thus, if a high susceptibility allele found in a variety of populations is rare or is absent in a given population, the most strongly associated allele in this population may be one that appears to be neutral or weakly predisposing in the other populations.

As noted above, the phenomenon of linkage disequilibrium (LD), the nonrandom association of particular alleles at linked loci, can complicate the interpretation of disease association studies. Some DRB1-DQA1-DQB1 haplotypes (specific combinations of linked alleles) are very much more frequent than any other combination of alleles. In any given population, the number of observed haplotypes is typically a very small proportion of all possible

haplotypic combinations. Within a given population, the association of particular DRB1, DQA1 and DQB1 alleles can be almost absolute. For example, DRB1*0301 (found in Africans, Caucasians and, more rarely, in Asians) is coupled, almost invariably to DQA1*0501 and DQB1*0201 whereas DRB1*0302 (found only in Africans) is coupled to DQA1*0401 and DQB1*0402. The set of DRB1*0405-containing haplotypes illustrate the population-related patterns of linkage disequilibrium. In Caucasians, this allele is coupled to DQA1*0301 and DQB1*0302. Among Africans, DRB1*0405 can be coupled to DQA1*0301 and DQB1*0201 and in the Japanese, it is coupled to DQA1*0301 and DQB1*0401. In the Philippines, DRB1*0405 is coupled to DQA1*0101 and DQB1*0503.

Strong linkage disequilibrium between closely linked loci such as DRB1, DQA1 and DQB1 (DQA1 and DQB1 are only 12 kb apart) may reflect a lack of crossing over between the loci or, more likely, selection for particular combinations of alleles. In principle, population admixture may also create linkage disequilibrium patterns but this is unlikely to account for the extensive disequilibrium found in virtually all human populations. The presence of linkage disequilibrium in human populations can, in any given population, make it difficult to identify which gene on a disease-associated haplotype is responsible for the observed association. Thus, a disease could show a strong association with a given DRB1 allele (e.g. DRB1*0301), but alleles at nearby loci (e.g. DQA1, DQB1, HLA-B or other non-HLA loci) that are in linkage disequilibrium with DRB1*0301 could, in principle, be responsible for the observed disease association. Some HLA haplotypes reveal patterns of linkage disequilibrium that extend toward the centromere to DPB1 and toward the telomere to HLA-B and HLA-A. These so-called 'extended haplotypes' (e.g. A1, B8, DRB1*301, DQB1*0201, DPB1*0101) have been taken as evidence for strong selection for particular haplotypic combinations. Because the patterns of linkage disequilibrium for alleles at the HLA loci can vary in different populations, studies of the same disease in different populations can be very instructive in helping to identify which gene or combination of genes on a given haplotype may be responsible for the observed disease association.

In addition to association studies, the role of genes in the HLA region in the pathogenesis of certain diseases has been demonstrated by linkage analysis. Linkage analysis follows the cosegregation of alleles with disease in large multiplex pedigrees. Many disease genes have 'incomplete penetrance' and, similarly, for alleles conferring disease predisposition,

many unaffected individuals in a pedigree may carry the susceptibility alleles. Given the confounding effect of incomplete penetrance for conventional cosegregation studies, a highly informative approach has been to focus on the analysis of the genetic markers only among affected sib pairs. The null hypothesis of no linkage would predict a random distribution among affected sib pairs for chromosomes or haplotypes detected with a given genetic marker (i.e. an HLA locus or a variable number tandem repeat locus). The expected random distribution for affected sib pairs is 25% with two identical-by-descent (IBD) haplotypes, 50% for those containing one IBD haplotype and 25% for those containing zero IBD haplotypes. Excess haplotype sharing among affected sib pairs relative to the distribution predicted by the null hypothesis is evidence of linkage. This approach (termed nonparametric) has the virtue of not requiring assumptions about parameters such as genetic dominance or recessivity, or estimates of penetrance, as do conventional (parametric) linkage analyses.

In general, linkage studies have properties distinct from association studies. In case-control studies, a positive association for a given marker and a specific disease will be obtained only if the marker allele is in linkage disequilibrium with the true disease gene, that is only if the marker locus is physically close to the disease locus, usually significantly less than 1 cM (1% recombination). In linkage studies, however, the marker need not be in linkage disequilibrium with the disease locus, only close enough so that recombination is uncommon. Linkage methods are expected to have reduced power when the disease allele is frequent in the general population. In a genome-wide scan for disease genes, when a genetic region has been identified by linkage methods, association (or linkage disequilibrium) methods are useful for homing in on a much smaller region. In terms of sample acquisition, a large number of family samples, however, is usually harder to obtain than samples for case-control studies.

Studies of multiplex families or of affected sib pairs also allow one to estimate the proportion of the total genetic risk attributable to a given genetic region defined by a specific marker; this approach involves calculating a value (λ_s) from the ratio of expected to observed affected sib pairs that share zero haplotypes. For IDDM, for example, the observed proportion of affected sib pairs sharing zero HLA haplotypes is about 0.06; the expected proportion is 0.25, yielding a λ_s for HLA of about 4.1. A proportion of about 50% for the total genetic risk for IDDM attributable to the HLA region can be calculated, making certain assumptions, from these values.

Risk estimates

The strength of disease associations can be assessed by a variety of risk estimates. The most commonly used risk estimate for HLA disease associations is the odds ratio or relative risk, the disease risk of an individual with a particular genetic marker relative to someone without the marker. This risk estimate, calculated as an odds ratio (see **Table 3**) from the frequency of a given HLA antigen, allele or genotype among patients and controls, is sensitive to the population frequency of the genetic marker. An epidemiologic risk estimate for prospective studies defines relative risk slightly differently (see **Table 3**). Retrospective HLA case-control studies almost invariably use the term 'relative risk' to denote the odds ratio. The statistical significance of the relative risk estimate (odds ratio) is often expressed as the 95% confidence interval around the calculated estimate. This risk estimate is independent of the disease incidence and provides no information on the likelihood of disease, given the marker. The risk of someone with the marker actually getting the disease is termed the absolute risk and is the product of the ratio of the marker frequency in patients and controls and the disease incidence (**Table 3**). Because the two risk estimates are defined differently, it can be instructive to consider both in evaluating disease association data. For example, in the case illustrated in **Table 4**, the frequency of one allele (Marker 1) is significantly increased among patients relative to controls and the frequency of another (Marker 2) allele is only very slightly increased. If one were to consider both alleles together as a marker (Marker 3) because, for instance, both alleles share a particular amino acid residue, the relative risk for the combined allele marker will go up but the absolute risk will go down

Table 3 Definition of risk estimates

Marker	
+ -	
Disease	+ a b
	- c d
a = number of patients with marker	
b = number of patients without marker	
c = number of controls with marker	
d = number of controls without marker	
Odds ratio (relative risk ^a)	$= \frac{ad}{cb}$
Absolute risk	$= \frac{a/(a+b)}{c/(c+d)} \times \text{disease incidence}$
Etiologic Fraction (population attributable risk)	$= \frac{(a/(a+b) - c/(c+d))}{1 - (c/(c+d))}$

^aThe relative risk used by epidemiologists for prospective studies differs slightly from the odds ratio used in case-control studies and is defined as $a/(a+c)/b/(b+d)$. For rare diseases where a and b are small relative to c and d , this expression approximates the odds ratio.

as a consequence of mixing a 'high risk' and a 'neutral' allele. Thus, it is inappropriate to argue that, because the relative risk is greater for the amino acid residue as a marker than for the high-risk allele that the susceptibility conferred by the high-risk allele is due to this shared amino acid residue.

A third measure of association, the 'etiologic fraction' or the 'population attributable risk', estimates the proportion of the disease incidence attributable to the marker (**Table 3**). This statistic, which is related to the normalized disequilibrium, D' , is unaffected by the frequency of alleles in the general population. In studies involving the genomic mapping of disease genes, this statistic is sometimes referred to as ' p excess' and estimates the association between a marker locus and nearby disease alleles.

The statistical measures to assess the significance of an observed disease association typically utilize the 2×2 table comparing the marker frequency in patients and controls and the chi-square test (Fisher's exact). When many comparisons are carried out, as is usually the case for the multiple alleles at an HLA locus, the likelihood of a chance association for one of the alleles must be considered. One approach to minimize the probability of a false positive association (type I error) due to multiple comparisons is to multiply the P value obtained for the associated marker by the number of comparisons made (Bonferroni's correction) yielding a P_c (corrected P value). This correction is conservative and, while minimizing type I error, may lead, for studies with moderate sample size but many alleles, to type II error, the failure to detect a true association. Another approach is to compare the allele frequency distributions of patients and controls rather than the frequencies of each individual allele. This is known as a 'heterogeneity' test (e.g. the G-test) and yields a P value for the probability that the two distributions are not different (homogeneous) and indicates which individual alleles have contributed to the heterogeneity.

Examples and issues in HLA disease associations

Virtually all HLA disease associations share certain general properties.

Predisposition to disease

The associated genes are 'normal' allelic variants rather than disease-causing mutations; they confer increased or decreased susceptibility to disease rather than the disease itself. Most individuals carrying the associated genes will not get the disease, indicating that additional environmental or genetic factors or

Table 4 Distribution of susceptibility alleles in patients and controls and risk estimates

	Patients	Controls	RR	AR	EF
<i>Frequency of marker</i>					
Marker 1	0.40	0.10	6.0	4.0 × disease incidence	0.33
Marker 2	0.50	0.40	1.5	1.25 × disease incidence	0.16
Marker 3	0.90	0.50	9.0	1.8 × disease incidence	0.80
<i>For ankylosing spondylitis</i>					
HLA-B27	0.94	0.09	158.4	10.4 × disease incidence	0.93

possibly stochastic events are required to elicit or trigger disease pathogenesis in predisposed individuals. The role of environmental 'triggers', such as bacterial or viral infections (or stochastic events), is evident from the observed concordance rates among monozygotic (MZ) twins. For IDDM, for example, the concordance rates for MZ twins are about 40–70%, depending on the HLA genotype.

Multiple genes

For most HLA-associated diseases, multiple genes, in addition to those in the HLA region, are involved in disease susceptibility. The polygenic nature of these disease associations can be inferred from comparing the concordance rates of HLA-identical siblings to those of MZ twins. For IDDM, for example, the concordance rates for HLA-identical sibs are 10–20% while those for MZ twins are 40–70%, implying that genes outside the HLA region are also involved. For IDDM, it has been estimated that about 45–50% of the total genetic risk can be attributed to the HLA region, based on the analysis of affected sib pairs. In addition, genome-wide scans in multiplex families have identified non-HLA genetic regions that may confer susceptibility to IDDM.

Combinations of MHC genes

In many cases, multiple genes within the HLA region appear to be involved in disease pathogenesis. For the DR4-associated susceptibility to IDDM, specific combinations of alleles at DRB1, DQA1 and DQB1 are required to confer high risk. Moreover, for IDDM, there is a *hierarchy* of risk ranging from highly susceptible to neutral to protective for different alleles, haplotypes and genotypes. In Caucasians, the DRB1*1501-DQB1*0602 haplotype is strongly protective for IDDM. Among susceptible genotypes, the heterozygote DR3/DR4, DQB1*0302 has the greatest risk for IDDM, significantly greater than the DR3/3 and DR4/4 homozygotes. One possible explanation for the dramatic DR3/4 effect on IDDM risk is the formation of *trans*-complementing DQ molecules encoded by the DQA1 locus of the DR3 haplotype (*0501) and the DQB1 locus of the DR4

haplotype (*0302) and those encoded by the DQA1 locus of the DR4 haplotype (*0301) and the DQB1 locus of the DR3 haplotype (*0201). For some diseases, alleles at the DPB1 locus, as well as those in the DR-DQ region appear to be involved in susceptibility. For pauciarticular juvenile rheumatoid arthritis, DPB1*0201 as well as DR8 (DRB1*0801) are strongly associated with disease and may be independent risk factors.

Interaction of host HLA genotype with pathogen genotype

For some HLA-associated diseases that are caused by an infectious pathogen, the HLA association may depend on the genotype of the pathogen. Invasive cervical carcinoma and severe cervical dysplasia result from infection with high-risk human papillomavirus (HPV) types such as HPV-16 or HPV-18. Only a small proportion of infected individuals, however, progress to cervical disease. Certain HLA types (HLA-B*07, DRB1*1501-DQB1*0602, DPB1*0401) are associated with cervical dysplasia and invasive cancer, but only with HPV-16-mediated disease.

The role of individual amino acid residues

The ability to identify specific alleles associated with a given disease has allowed the comparisons of associated sequences with other closely related alleles and made possible the identification of specific polymorphic amino acid residues that may be involved with the disease pathogenesis. Disease-associated alleles often differ from nonassociated alleles at single amino acid residues or at a single polymorphic motif, implicating these positions as critical in some aspect of immune function, such as peptide binding and presentation. For example, the PV-associated DQB1*0503 allele differs from *0501 and *0502 only at position 57; DQB1*0503 encodes Asp whereas *0501 encodes Val and *0502 encodes Ser at this position. The substitution of a negatively charged residue for a neutral residue at position 57 is thought to affect the formation of a salt bridge between the α and β chain. In IDDM, there is a

general correlation of DQB1 alleles with Asp at position 576 and low risk for IDDM; there are, however, several exceptions to this pattern. In general, the risk associated with an allele cannot be predicted by a single amino acid position but only by *combinations* of motifs assembled as alleles, haplotypes, and genotypes.

Summary

A wide variety of human diseases have been associated with specific alleles at the HLA class I and class II loci. In a small subset of these diseases, the association can be attributed to linkage disequilibrium with a linked non-HLA locus. For the majority of these diseases, however, it appears that specific HLA molecules confer increased susceptibility or protection from disease. In many cases, it is specific combinations of alleles at HLA loci that appear to determine disease risk and for some diseases, there is a hierarchy of risk depending on the HLA genotype. The immunological mechanisms underlying the disease associations are still not fully understood but are likely to involve the manner in which peptides are bound and presented to the T cell by the HLA molecules encoded by the disease-associated alleles. DNA-based typing methods, capable of distinguishing the many allelic variants within a serologic HLA type, have been highly informative in identifying specific alleles, haplotypes and genotypes and in estimating the disease risk for the associated markers. These studies promise to have significant

clinical value in differential diagnosis, prognosis and in the identification of predisposed individuals; the identification of at-risk individuals offers the hope of a better understanding of pathogenesis and, ultimately, of disease prevention.

MHC, EVOLUTION OF

Jan Klein, Department of Immunogenetics, Max-Planck-Institute for Biology, Tübingen, Germany

The presence of major histocompatibility complex (MHC) class I and class II genes has been demonstrated in all classes of jawed vertebrates (gnathostomes); no trace of these genes has thus far been found in jawless vertebrates (agnathans, represented by hagfish and lamprey) or in nonvertebrate chordates (cephalochordates, urochordates). Whether agnathans truly lack MHC genes or possess genes that are very different from those of the gnathostomes remains an unanswered question. From the rate of nonsynonymous substitutions it can be calculated that the class I and class II genes diverged more than 500 million years ago and hence before vertebrate radiation, but this estimate has a large range of error.

In all jawed vertebrates that have been studied, the organization of the MHC genes (and, by implication,

of the MHC molecules) is the same: 1) the genes fall into two classes (I and II); 2) in each class there are multiple gene families; 3) in each family there are two types of genes, A and B, encoding the α and β polypeptide chains of the MHC heterodimers, respectively; 4) the exon-intron organization is largely conserved in the various genes of the same class; 5) the polymorphism, when present, is concentrated in the same exons (in class I genes in exons 2 and 3, in class II genes in exon 2); and 6) within the variable exons, the polymorphism is concentrated into 3–4 short segments. These observations, particularly the last two, imply that the function of the MHC molecules has been conserved for at least 400 million years, since the emergence of the jawed vertebrates. The focusing of the polymorphism onto the

putative peptide-binding regions (PBRs) in all gnathostome classes suggests that the MHC function has been, from the beginning, to bind peptides, presumably for presentation to T cell receptors (TCRs), and thus to initiate the anticipatory (adaptive) immune response. It can therefore be expected that MHC and TCR (and by extension also immunoglobulins, Ig) emerged simultaneously, and that their emergence marked the appearance of the anticipatory response. By this reasoning, the anticipatory immune system is an innovation restricted to vertebrates or perhaps to chordates, as experimental observations indeed indicate.

The primordial MHC gene seems to have been assembled from two or three other genes, each of which originally had a different function. One of the contributing genes came from the immunoglobulin superfamily, another from a family of genes encoding structures with an α helix rising from a β -stranded platform (= MHC fold), and the third from a gene encoding membrane-anchoring and possibly signal-transmission structures. The identity of the gene family that donated the peptide-binding domains characterized by the MHC fold is not known. The HSP70 family has been proposed as a possible candidate, but newer data on the tertiary structure of HSP70 proteins do not support this suggestion. Another possible candidate is the proteasomal gene family, but here, too, no significant structural similarity to the peptide-binding domains of the MHC molecules has been found. In the tertiary structure, the MHC peptide-binding domains superficially resemble proteins of the interleukin 8 (IL-8) family, and in the primary structure there is a weak sequence similarity between MHC proteins and the endothelial cell protein receptor (EPCR). The significance of these similarities is obscure.

It is generally assumed that the primordial class I and class II genes arose from a common ancestor by gene duplication. Whether this ancestor had the structure of a class I or class II gene is controversial. The most parsimonious hypothesis seems to be that the ancestor resembled a class II gene and that the first MHC molecules were homodimers in which each protein chain contributed one half of the peptide-binding module. A duplication of this gene and subsequent divergence of the two copies produced the primordial class II A and B genes encoding, respectively, the α and β chains of the class II heterodimers. A second round of duplication followed by a deletion–fusion process then created a primordial class I gene with two exons specifying the two halves of the peptide-binding module. The product of this gene came to associate noncovalently with a single domain encoded in another member of the immunoglobulin superfamily, the β_2 -microglobulin gene.

The process of duplication (expansion) and deletion (contraction) of the class I and class II genes has continued throughout subsequent MHC evolution and has led to the emergence of new MHC gene families and the demise of old ones. In bony fish, for instance, every major order possesses different MHC class I and class II gene families, each derived from a separate ancestor. The families persist for a variable length of time. In eutherian mammals, for example, the class II DR, DQ, DP, DN/DO, and DM families are shared by the different orders, whereas the primate class I A, B, C family is restricted to this order and possibly only to one suborder. Within each MHC class I or class II family, different genes are functional for a variable length of time. Thus, for example, while orthologous DQB and DPB genes have apparently remained functional for the entire period of primate evolution, functional DRB genes have been replaced at least three times by their paralogs: in prosimians, New World monkeys, and Old World monkeys (together with apes). The non-functional copies, can, however, persist as pseudogenes for a long time. The primate DRB6 gene, for example, may have been nonfunctional for more than 30 million years.

The average substitution rates at the synonymous and nonsynonymous PBR sites of the MHC genes are 1.2×10^{-9} and 5.9×10^{-9} per site per year, respectively. The synonymous rate is lower and the nonsynonymous rate higher than that of most non-MHC genes. The MHC genes therefore contain a region (PBR) that evolves faster than most other genes, while the rest of the MHC gene evolves at a comparable or a lower rate. In contrast to other genes, however, the MHC genes do not contain regions highly conserved over long evolutionary periods. Although some amino acid residues at certain positions are invariant or nearly so in the encoded proteins, they are scattered, and sharing of long stretches between distantly related molecules is rare. Cloning of MHC genes from unrelated taxa is therefore always a challenge not obviated by the steady accumulation of sequences from a variety of vertebrates.

MHC genes are subjected to both positive (balancing) and negative (purifying) selection. The positive selection is restricted to the nonsynonymous PBR sites, whereas the negative selection affects various nonsynonymous sites scattered over the rest of the coding sequence. The intensity of the positive selection has been estimated to be less than 0.02. (For comparison, the selection intensity exerted by the causative agent of malaria on the hemoglobin S allele is 0.3.) A selection coefficient this low will therefore be difficult to measure experimentally in

any but the most prolific vertebrate species. The selection is presumably effected by parasites or would-be parasites via the interaction of parasite-derived peptides with the PBR of functional MHC molecules. The mechanism of selection is believed to be heterozygous advantage (an MHC heterozygote being protected from more parasites than an MHC homozygote), although a case for frequency-dependent selection (protection effected for as long as an allele is rare) has also been made. The intensity of the negative selection can be expressed in terms of a functional constraint on the non-PBR site. On a scale on which 0 indicates a complete conservation (no amino acid replacements are allowed) and 1 a complete absence of conservation (any substitution is allowed as in a nonfunctional gene), the MHC genes score a functional constraint value of 0.33, the average for non-MHC genes being 0.189. Hence, functional MHC genes are less constrained in terms of purifying selection than most non-MHC genes.

Balancing selection is responsible for the maintenance of MHC alleles in the population, without fixation (attainment of frequency of 100%), for periods in excess of those expected for neutral alleles. This long allele persistence time has two major consequences. First, during their tenure in the population the polymorphic alleles are in a position to diversify by additional mutations. A polymorphic allele incorporates an additional nonsynonymous mutation at a PBR site, or a synonymous mutation on average every 1–4 and 3–5 million years, respectively. Alleles differing in up to 10% of their coding sequence are a common appearance at functional MHC loci. Second, the allelic lineage persistence time can be longer than the lifespan of a species and the MHC polymorphism is therefore transmitted from ancestral to descendant species in a trans-specific manner. Some MHC allelic lineages have been shown to be more than 30 million years old; these must have 'survived' several rounds of speciation.

Old allelic lineages are often characterized by the presence of diagnostic motifs – short, largely invariant stretches of sequences idiomatic to a particular group of alleles. Sequence motifs, which are usually part of the PBR, are normally indicative of shared ancestry, particularly if a given group of alleles has more than one motif in common. Evidence is accumulating, however, that identical or very similar motifs can also arise independently in different genes, presumably by selection. Some motifs, particularly those shared by the MHC genes of very distant taxa, therefore represent instances of convergent evolution, possibly driven by the need to respond to similar parasite-derived peptides.

Although the class I and class II loci occur in clus-

ters, they are, in all vertebrates thus far studied, intermingled with other loci. The latter are often referred to as class III loci although they are occupied by a heterogeneous group of mostly unrelated genes. In bony fish (represented by the zebrafish), on the other hand, the class II loci are dispersed to two different chromosomes, the class I loci are on yet another chromosome, and each of the clusters is associated with class III loci different from those in mammals. The LMP2 and LMP7 loci, which in mammals are part of the class II cluster, are in the zebrafish in the class I cluster. Since the LMP loci are functionally tied to the class I loci, the zebrafish arrangement might be ancestral to that found in mammals. The zebrafish MHC organization rules out the suggestion that class I and class II must be linked to coordinate their expression. Which of the two types of MHC organizations (the human or the zebrafish type) is more ancient remains an unresolved question.

Genes mapping to the major histocompatibility complex (MHC) encode the cell surface glycoproteins (class I and class II) recognized by self-monitoring and alloreactive T lymphocytes, the LMP2 and LMP7 components of the proteasome complex, two chains that comprise the transporter associated with antigen-processing (TAP) complex, the α and β chains of the H2M (mouse) or HLA-DM (human) molecule, the C4 component of the complement cascade, and the α and β forms of tumor necrosis factor (TNF). The MHC class I molecules were initially identified as the strong transplantation antigens, while the class II glycoproteins were first described as the immune response (Ir) gene products. In addition to the class I genes H2-K, H2-D and H2-L (mice) and HLA-A, -B, and -C (humans), there are multiple loci for class Ib genes, H2-Q, T, and M (mouse) and HLA-E, F, G, H, I and J (human). DNA sequence analysis has also demonstrated the existence of many more genes that have not been associated with any product. Whether there is an underlying biological reason why this set of genes should be inherited as a complex has not been clarified.

T cell targeting and effector function

The class I and class II MHC glycoproteins perform a central immunological function in focusing CD8⁺ and CD4⁺ T lymphocytes, respectively, to the surface of appropriate cells. The underlying principle is the same in both cases. The α/β T cell receptor (TCR) heterodimer recognizes a peptide bound into an active site located in the most external domains of the MHC glycoprotein. In the adult, the 10^7 or more possible TCR specificities are capable of monitoring self MHC molecules that are associated with a great variety of nonself peptides derived, for instance, from invading viruses or bacteria. The CD8 and CD4 molecules are considered to play an accessory role in this cell-interaction process by acting as coreceptors for the TCR and by further stabilizing TCR/MHC interactions by binding to conserved regions on the MHC class I or class II proteins.

The anatomical distribution patterns of the MHC molecules determine the spectrum of T cell targeting. For example, MHC class I glycoproteins are expressed on nearly all nucleated cell types throughout the body. This means that virus-infected cells in the various organ sites can signal evidence of abnormal

cell events, such as viral infection, to recirculating CD8⁺ virus-immune T cells. These lymphocytes can potentially kill virus-infected target cells and thus terminate the progression of the infectious process. An exception to this rule is found in the brain where some cells, especially sensory neurons, remain MHC class I negative. This may be the reason that herpesviruses can persist, for instance, in the trigeminal ganglia.

Under normal circumstances, the class II molecules are distributed mostly on B lymphocytes, dendritic cells and macrophages, all of which are found in lymphoid tissue. This serves to focus the CD4⁺ T cells to the lymph nodes and spleen. A primary function of the CD4⁺ T cell subset is to secrete cytokines, such as interleukin 2 (IL-2) and IL-4, which promote the growth and differentiation of other lymphocytes, such as B cells. Further, the responses of the CD4⁺ lymphocytes are necessary for T-dependent antibody production. As such cytokines function essentially at short range, it is essential that the CD4⁺ helper T cells and B cells make direct contact through TCR/MHC interactions.

The part played by the MHC in normal immunity can be illustrated by giving a somewhat speculative account of what happens during the primary response to a poxvirus. The virus invades through the skin and is immediately transported, either as free infectious particles or in the cytoplasm of 'veiled cells' (a type of dendritic cell), via the lymphatics to the regional lymph node. Some cells, including macrophages, are infected. Virus uncoating follows, the replication process is initiated, and new virus proteins are made. A proportion of the protein is degraded to peptide fragments, perhaps by the proteolytic proteasome complex. Some of these peptides are transported into the endoplasmic reticulum (ER), via the TAP complex, where binding to intracellular class I protein occurs if the peptides have sufficient affinity for the class I molecule. The class I-peptide complex is then transported to the cell surface, where it can be recognized by CD8⁺ T cells expressing the appropriate α/β TCR. Such lymphocytes are present in unstimulated lymphoid tissue at a frequency of $<1:600\,000$ and increase to as much as 1:2000 within 6 days after primary exposure to the virus. The CD8⁺ cytotoxic effectors are first detected on day 5, when they exit the lymph node and localize

to other tissues where there are infected cells expressing the same class I–peptide complex.

Some of the virus that enters the lymph node will be bound by B cells expressing surface immunoglobulin (Ig) specific for determinants on the viral coat glycoproteins. This Ig–virion complex is internalized and degraded in lysosomes. Peptides derived from proteins that are both internal and external to the virus particle can then potentially associate with MHC class II molecules and be expressed on the cell surface where there is a concomitant increase in the total level of class II glycoprotein expression. As a consequence, helper CD4⁺ T cells specific for any viral peptide bound to self class II proteins are focused on to the B lymphocytes that can potentially secrete neutralizing antibody specific for the determinant recognized initially on the invading pathogen. The interleukins produced by these helper T cells promote the growth and differentiation of the responding B lymphocytes.

The class I and class II molecules thus act as ‘signposts’ to direct the CD8⁺ and CD4⁺ lymphocytes to appropriate locations, first in lymphoid tissue and later in organ sites of virus growth. Patterns of cytokine secretion are central to these processes. The level of cell surface MHC class I expression is enhanced by interferon- α /interferon- β (IFN α / β) which is produced by many virus-infected cells. An even more potent stimulus for both class I and class II expression is IFN γ , which is secreted by activated CD8⁺ and some CD4⁺ T cells. In the brain, for instance, astrocytes can be induced to become MHC class I and class II positive following exposure to IFN γ , while sensory neurons remain negative. Such astrocytes can function as potent stimulators of CD4⁺ T cells.

Although much less is understood regarding the role of the class Ib proteins in protecting individuals from infectious pathogens, some recent evidence has revealed that these molecules may play an important part in generating immune responses to certain classes of bacteria. When identifying the nature of the maternally transmitted minor histocompatibility antigen, Mta, murine H2–M3 complexes were shown to bind a mitochondrially derived peptide that contained an N-formyl methionine at the N-terminus. This modification of the peptide is unique in that it is produced only in eubacteria, mitochondria and chloroplasts. It was later shown that, during infection with the gram-positive bacteria *Listeria monocytogenes*, CD8⁺ T cells were generated that recognize M3 molecules associated with an N-formylated peptide derived from a bacterial protein. As the MHC class Ib molecules are far less polymorphic than the conventional class I proteins, understanding

the CD8⁺ T cell responses to these antigens provides insight to design vaccine strategies for populations where the classical MHC molecules are genetically diverse.

Polymorphism, duplication, repertoire and tolerance

Obviously, this ‘self-surveillance’ system only operates if ‘nonself’ peptide(s) can associate with MHC molecules to form an immunogenic complex, i.e. one for which there is a complementary TCR. This is not always the case. Evidence of a complete absence of response can be found for particular MHC molecules, even with large viruses such as vaccinia. Evolution has compensated for this possibility in several ways. The first is that both the H2 and HLA systems are extremely polymorphic. The possibility of utilizing more than 100 allelic forms of the MHC proteins means that there is little likelihood of a total failure of T cell response to a particular pathogen throughout the species. Also, there are new alleles that arise within populations to add even more diversity. For example, studies of small native populations in North and South America have revealed that the HLA-B locus has the potential to evolve rapidly in limited populations. In this instance, new loci were generated by intralocus recombination. Whether this reflects a change in response to a pathogen that was introduced to that particular population is uncertain. The second mechanism is the duplication of genetic loci that seem to be functionally identical. A heterozygous individual expresses as many as six class I glycoproteins (H2-K, H2-D and H2-L in the mouse and HLA-A, -B and -C in humans). MHC class II complexes comprise two transmembrane glycoproteins, α - and β -chains. In the mouse there are two isotypes of class II molecules, I-A and I-E, while humans express three types of class II molecules, HLA-DP, -DQ and -DR.

This duplication of class I and II MHC loci is not devoid of potential negative consequences for immune responsiveness. The problem is that the immune system must learn to be tolerant of self peptides presented in the context of self MHC molecules. The larger the number of self MHC glycoproteins, the greater is the deletion of potential TCR specificities with high affinity for self. This process of negative selection of the TCR repertoire occurs, at least initially, in the thymus. There is good evidence that the presence of a particular MHC complex during thymocyte ontogeny results in the deletion of T cells which express a TCR that has too high an affinity for the MHC molecule. The consequence may, for instance, be the effective deletion of

all T cells expressing a particular TCR V_β gene. This can obviously act to decrease the pool of potential T cell responder specificities. However, it is also likely that a major role of the thymus is to select positively for thymocytes expressing TCR with a low or intermediate affinity for self class I or class II MHC glycoproteins, as precursors for mature T cells that can potentially recognize the same MHC molecule modified by a foreign peptide. Whether the apparent convergence in the existence of the class I MHC loci in mice (H2-K, H2-D and H2-L) and humans (HLA-A, -B and -C) as a trinity is indicative of an optimum evolutionary balance between the need to maintain self-tolerance and the capacity for immune responsiveness, or is simply a reflection of the nature of an ancestral gene pool, is not clear.

Immunological surveillance and graft rejection

Holes in the TCR repertoire resulting from the need to maintain self-tolerance may not normally constitute a problem for the specific host response to viruses or bacteria, as any pathogen is likely to incorporate a great many nonself peptides that can potentially associate with one of the self MHC glycoproteins. This thinking can legitimately be extended to the B cell lymphoma induced by Epstein-Barr virus which, at least for Caucasians, may normally be held in check by T cells. However, the effectiveness of such surveillance for tumors that are not induced by viruses is likely to be very much constrained, especially as there is no obvious reason why a particular oncogenic change should be characterized by the expression of novel peptides that bind to MHC molecules, unless the level of some poorly expressed gene is upregulated to a point where sufficient peptides from that protein are generated and available to bind MHC molecules. Also, the selection pressure exerted by immune T cells on tumors that are immunogenic can lead to the emergence of variants that no longer express the target MHC class I molecule. Further, to initiate an immune response the responding T cell must receive not only a signal from a cognate TCR/MHC interaction, but also costimulatory signals from accessory molecules expressed on the tumor cell. Gene therapy studies have suggested that strategies to express MHC and/or costimulatory molecules on tumor cells may help to initiate a tumor-specific immune response *in vivo*.

The account so far has concentrated on the part played by the MHC in the monitoring of self by T lymphocytes, the phenomenon known as MHC restriction. However, the MHC is named for, and

was historically defined by, the phenomenon of allo-reactivity that is the central feature of graft rejection. Current thinking is that the high frequency of T cells ($>1:1000$ spleen cells in the mouse) specific for any foreign MHC glycoprotein reflects that a TCR which recognizes a particular self-derived MHC-peptide complex will also bind to one or other nonself MHC molecules (alloantigens). However, this does not necessarily mean that alloreactivity is simply an epiphenomenon of the self-surveillance mechanism. It is possible that the fine tuning of host response represented by the thymic T cell-MHC interactions has derived in evolutionary time from a much more primitive mechanism analogous to that operating, for instance, to prevent one colony of corals from parasitizing another. The precursors of the TCR genes are likely to have been a considerably less diverse set of genes encoding cell interaction molecules.

Possible physiological functions

The MHC may also have additional functions which are not directly related to the specific immune response. There is support from both rat and mouse experimental systems for mating preference between MHC-different individuals. Perhaps particular MHC-peptide complexes have pheromone-like properties when, for instance, they are excreted in urine. If this is so, it would provide an obvious mechanism for promoting heterozygosity and thus polymorphism. One problem with this concept is that wild mice maintain in discrete populations, or demes, and tend not to mate with mice from a different deme that is in the immediate vicinity. Further functions for which some evidence has been presented in the past include an influence on patterns of lymphocyte recirculation and the capacity to influence the association of somatic cells other than T lymphocytes. However, there are now a number of other cell surface molecules that may be better candidates for such roles.

Cellular and humoral immunity

The primary role of the MHC in immunity is to alert T lymphocytes to changes in the surface integrity of other cells, so that they can be dealt with in a way that is appropriate for maintaining the integrity of the milieu interieur. The MHC class I and class II molecules define the nature of self to the immune system. If discovered today, the MHC might be more appropriately named the 'self-surveillance complex'. Unlike the Ig molecules, which can be produced in

large numbers by a single plasma cell, the T cells themselves are the effectors of cell-mediated immunity. Antibodies bind well to foreign molecules (e.g. viral coat proteins), and do not normally interact with the MHC glycoprotein-peptide complex which targets recirculating T lymphocytes. The MHC is thus the key operator in a 'law of conservation of T cell function'. The comparatively rare helper and effector T cells are focused on to the cell surface, do not recognize free virus particles, and are not blocked by the much more prolific Ig molecules.

MHC PEPTIDE-BINDING SPECIFICITY

Juergen Hammer and Francesco Sinigaglia, Roche Milano Ricerche, Milan, Italy

Major histocompatibility complex (MHC) molecules are highly polymorphic membrane glycoproteins that bind peptide fragments of proteins and display them for recognition by T cells. Their function is to present self antigens in the thymus for tolerance induction and foreign antigens in the periphery for immune response. MHC peptide recognition by T cells is thus the means by which the organism discriminates between self and nonself.

One of the hallmarks of class II MHC molecules is their extraordinary allelic polymorphism. Each allelic form of MHC molecules binds a large array of different peptides to ensure T cell-mediated immunity against the spectrum of pathogens, and yet T cells must be tolerant to a sufficient number of self proteins to avoid the possibility of potentially harmful immune responses against self antigens. Recent advances have increased our understanding of the molecular events in peptide interaction with MHC molecules and allowed for the systematic

identification of antigenic sites in natural self and foreign proteins.

The MHC peptide-binding groove

The molecules encoded in the MHC complex form a family of highly polymorphic glycoproteins. Of these MHC proteins, the best characterized are the class I (HLA-A, -B, -C in humans and H-2K, -D, -L in mice) and class II (HLA-DR, -DQ, -DP in humans and I-A, I-E in the mice) molecules which present peptides to CD8⁺ and CD4⁺ lymphocytes, respectively. Class I molecules are dimers of a membrane-inserted heavy chain and a soluble light chain, the β_2 -microglobulin. Class II molecules are $\alpha\beta$ dimers of similar size, both of which are transmembrane proteins. The three-dimensional structure of several class I and class II molecules has been determined by X-ray crystallography. The class I peptide-binding site is formed by the two membrane-distal domains of the heavy

chain and is composed of a floor of eight β strands flanked by two α helical walls. The organization of the class II peptide binding site is similar to the class I binding site, even though it is formed by the membrane-distal domains of both class II chains, to which each contribute one α helix and four β strands. The β sheet floors and helical walls define a groove of suitable dimension for occupancy by 8–10 peptide residues in both MHC classes.

Despite an overall similarity of the class I and class II groove, detailed differences with major functional consequences have been identified. The class I cleft is blocked completely at both ends by bulky amino acid side-chains, while the class II cleft is open due to a replacement and/or a repositioning of these blocking side-chains. Consequently, the majority of class I binding sequences are short peptides in the range of 8–10 residues. In contrast, the open class II cleft allows peptides to extend out, enabling as a result, the binding of a broader range of peptide lengths, typically 12–24 residues.

Sequence-independent MHC peptide binding

MHC molecules must be able to bind a large array of different peptides to ensure T cell-mediated immunity to the antigenic universe. This broad binding capacity arises from the interaction between conserved MHC residues and the peptide main chain, thereby providing a sequence-independent affinity for peptide ligands. For class I, the binding of the peptide main chain involves topographically clustered MHC residues at both ends of the binding groove. These residues interact with the free N- and C-terminal groups of the peptide. The critical contributions of both termini to the affinity of peptide ligands, and the fact that both ends of the groove are closed (see above), explain the strong bias for the stable binding of short peptides. For class II, the location and the identity of the conserved residues interacting with the peptide main-chain are very different. Instead of being clustered at the ends of the cleft, they are distributed along the class II groove. Consequently, the peptide main chain is kept in close contact with the MHC cleft, resulting in a relatively flat conformation of class II-bound peptides. In contrast, prominent kinks are observed in class I-bound peptides, and even a limited amount of bulging is accommodated while the N- and C-terminal binding is maintained.

Figure 1 Pockets in the HLA-DR1 peptide binding site. Side view of the molecular surface of the HLA-DR1 peptide-binding site with the influenza hemagglutinin peptide 306–318. Peptide side-chains are labelled in one letter code. (Reproduced, by copyright permission, from *Nature* 1994; **368**: 220.) (See also color **Plate 5**.)

Sequence-dependent MHC peptide binding

The sequence-independent network of hydrogen bonds between conserved MHC residues and the peptide main-chain gives rise to a broad, but not unlimited, peptide-binding capacity. Indeed, most natural peptide sequences lack the characteristics necessary to bind to MHC molecules, because peptide main-chain interactions are not the only mode of MHC binding. Some of the peptide side-chains contact residues within the MHC cleft and increase the overall binding affinity and specificity of the associated peptides (anchor residues); others interfere with residues of the MHC cleft and reduce binding (inhibitory residues). These sequence-dependent interactions are due to the irregular surface of the MHC cleft. MHC side-chains protrude into the cleft and form pockets or ridges, resulting in strong preferences for interaction with particular amino acid side-chains (**Figure 1**).

Notably, most pockets in the MHC groove are

Table 1 MHC motifs

MHC molecules	Peptide positions								
	1	2	3	4	5	6	7	8	9
HLA-A*0201	–	L	–	–	–	V	–	–	V
		M							L
HLA-B*2705	–	R	–	–	–	–	–	–	L
									F
HLA-DRB1*0101	Y	–	–	M	–	A	–	–	L
	F			L		G			M
HLA-DRB1*1101	W	–	–	M	–	R	–	–	–
				L		K			

shaped by clusters of polymorphic MHC residues and are thus of distinct chemical and size characteristics in different MHC alleles. For example, a negatively charged side-chain in one MHC molecule may preferentially interact with positively charged peptide residues, while a positively charged side-chain in another MHC molecule may only bind to negatively charged peptide residues; similarly, a small side-chain in one MHC molecule may greatly extend a pocket and allow for interaction with many different amino acid residues, while a large amino acid side-chain in another MHC molecule may completely block access to this pocket. MHC alleles can therefore be characterized by differences in the precise nature and position of polymorphic pockets, thereby playing a major role in allele-specific peptide binding.

MHC peptide-binding motifs

The interaction of peptide side-chains with pockets of the MHC cleft imposes sequence requirements on the binding peptides. These requirements are summarized in peptide-binding motifs. The characterization of large, MHC-selected peptide pools was a breakthrough for the analysis of MHC binding motifs, for it allowed the generalization of rules for peptide binding to MHC molecules. Class I motifs were analyzed by the pooled peptide sequencing technique; that is, the elution of endogenous class I peptide pools and their subsequent analysis by Edman sequencing. The length restriction of class I-bound peptides leads to a natural alignment of class I-bound peptides, thus allowing the identification of position-dependent preferences for particular amino acid side-chains (class I anchors) by sequencing total mixtures of the eluted peptides. Class II motifs were identified by the analysis of large peptide pools selected from M13 bacteriophage peptide display libraries comprising several million random nonamer peptides. Sequence analysis of the DNA encoding the displayed peptides led to the identification of class II anchors. Both pool sequencing and screening of phage libraries have been used for the identification of several allele-specific class I- and class II-binding motifs, respectively. These motifs generally consist of 2–4 anchor positions that are at fixed distances from one another (Table 1).

Prediction of MHC-binding peptides

The discovery of motifs through pool sequencing and phage library screening would imply simple rules for peptide–MHC interaction. Much evidence has indicated, however, that these motifs were only the tip of the iceberg, and that the rules for MHC peptide

binding are much more complex because: 1) inhibitory residues are as important for MHC peptide binding as anchor residues and binding studies have revealed both position- and allele-specific properties of such inhibitory residues; 2) apart from the main anchor positions identified by pool sequencing and phage library screening, additional ‘secondary’ anchors were found to be important for MHC peptide binding, thus rendering difficult the prediction of MHC binding sequences by using ‘simple’ MHC motifs. Consequently, new quantitative approaches have been developed that allow for a more complete characterization of MHC peptide-binding specificity: the effects of all natural amino acids at each peptide position are quantitated by using multiple-peptide synthesis technology, together with new high-flux *in vitro* binding assays. The resulting quantitative motifs are thus like ‘fingerprints’ of the MHC clefts, as they reflect, as the sum of all peptide side-chain values, the architecture of the polymorphic groove. Effective predictive algorithms for identifying antigenic determinants in proteins or producing custom peptides with defined binding properties have been developed. These methods involve systematically scoring the positive and negative effects of a full set of amino acid substitutions on binding to class II molecules at each position of a peptide, and representing the results for any specific sequence as the sum of the values for each position. These new methods represent a powerful new approach to picking out regions of large proteins representing dominant determinants for use in peptide-based vaccines.

MHC antagonists

The identification of rules for peptide binding to MHC class II molecules could also have interesting applications in the treatment of autoimmune disease.

Autoimmune diseases result from the activation of self-reactive T cells by autoantigens. A striking characteristic of autoimmune diseases is the increased frequency of certain HLA class II alleles in affected individuals. Moreover, as demonstrated in rheumatoid arthritis and insulin-dependent diabetes mellitus, for example, alleles that positively associate with autoimmune diseases share unique amino acid residues in the hypervariable regions involved in peptide binding. Although the pathogenesis of autoimmune diseases is not known, one possibility is that disease-associated HLA class II molecules are able to bind and to present autoantigenic peptides to T cells. These peptides activate autoreactive CD4⁺ T cells, which in turn induce a cascade of chronic inflammation.

Blocking the antigen-presenting activity of disease-associated HLA class II molecules could represent an important way to prevent and possibly treat autoimmune diseases.

The knowledge of the anchor position, as well as the other general rules for peptide binding to MHC molecules, should prove very useful for the design of MHC-specific antagonists. This strategy ought to be directed towards the development of a low molecular weight antagonist, possibly nonpeptic, that blocks the peptide-binding site of disease-linked class II MHC molecules. Such an antagonist is expected to interfere with the presentation of antigenic peptide ligands, including those involved in the activation of autoimmune T cells.

MHC RESTRICTION

Ethan M Shevach, Laboratory of Immunology, National Institutes of Allergy and Infectious Diseases, National Institutes of Health, Maryland, USA

Although the concept that multiple cell types must interact to generate an immune response was firmly established in the 1960s, the possible role of cell surface antigens such as the major histocompatibility complex (MHC) in restricting intercellular interactions was not considered until a series of experiments was performed in the 1970s, which established that virtually all intercellular communication in the immune response, including the regulation of antigen-specific T lymphocyte proliferation, antibody production, delayed hypersensitivity, and the generation of cytotoxic T lymphocytes (CTLs) required that the interacting cell types share specific regions of the MHC. Subsequent studies have established that this requirement for MHC compatibility between interacting cells is intimately related to the ontogenetic development of T lymphocytes in the thymus.

Macrophage/T lymphocyte interaction

Primed T lymphocytes and T cell lines/clones can be stimulated to proliferate *in vitro* by antigen only if a specialized antigen-presenting cell (APC) is also present in the culture. Cells that perform APC function include dendritic cells, macrophages and activated B lymphocytes. In 1973, Rosenthal and Shevach took antigen-primed CD4⁺ T lymphocytes from one strain of inbred guinea pig and attempted to stimulate them to proliferate with antigen on the surface of macrophages from another strain. Antigen-induced T cell proliferation could only be observed when the macrophages and T lymphocytes were derived from the same strain. One possible explanation for the failure of histoincompatible combinations of macrophages and T cells to interact was that the mixed leukocyte reaction which was produced when allogeneic combinations of macrophages and

T cells were cocultured led to inhibition of cellular interaction. However, macrophages from F1 animals were fully capable of presenting antigen to T lymphocytes from either of the parental strains even though a low-level mixed leukocyte reaction was observed in such cultures. The conclusion drawn from these studies was that MHC identity was required for effective macrophage/T lymphocyte interaction. These studies in the guinea pig model were confirmed and extended with congenic and recombinant mouse strains to establish firmly that the products of the I-region of the MHC (class II antigens) were responsible for mediating this interaction. In addition, studies on the role of the macrophage in the induction of the T helper cell *in vitro* demonstrated similar genetic restrictions involving I-region products. The transfer of delayed hypersensitivity *in vivo* also required that the donor and recipient be MHC compatible. In this situation, it is necessary for the resident APC population in the recipient skin, the Langerhans cells, to share MHC antigens with the T lymphocytes of the donor.

One of the most instructive experiments performed during the course of studies investigating MHC restriction in macrophage/T lymphocyte interaction was derived from the analysis of the response of T cells to antigens, the response to which is controlled by specific immune response (Ir) genes. MHC-linked Ir genes had been previously identified that controlled the capacity of certain strains of a species to recognize simple antigens. Although macrophages from either parental strain were capable of presenting complex antigens such as ovalbumin to F1 T cells, primed T cells from F1 animals made by mating responder and nonresponder parents failed to recognize simple antigens, the responses to which are controlled by specific Ir genes associated with macrophages from the nonresponder parent. Thus, if strain A was a responder to a given antigen, while strain B was a nonresponder, (A × B)F1 T cells which are responders could only be activated by antigen in association with strain A, but not strain B macrophages. The unresponsiveness of the F1 animal to antigen associated with APC of the nonresponder parent can now be explained by the failure of antigenic peptides from simple antigens to bind to the MHC class II molecule of the nonresponder parent so as to form an effective complex that can be recognized by the T cell receptor. In contrast, complex antigens can be broken down to multiple peptides and some of these are likely to bind to the polymorphic MHC class II molecules of all members of a species, resulting in complexes which can be recognized by the TCR from any strain.

T lymphocyte/B lymphocyte interaction

The first experiments to demonstrate directly the failure of cooperation of histoincompatible T and B lymphocytes to generate an antibody response were performed by Katz and coworkers. In these studies, F1 recipients were injected with carrier primed T cells from one of the parental strains, irradiated 24 h later, and then injected with B lymphocytes from the other parent primed to a hapten on a heterologous carrier. The reconstituted animals were then immunized with the appropriate hapten-carrier conjugate and the antihapten response was measured 7 days later. If the carrier-primed T lymphocytes and hapten-primed B lymphocytes were derived from the same parental strain, an antihapten antibody could be measured. The failure of histoincompatible helper T lymphocytes to collaborate with hapten-specific B lymphocytes was not secondary to an 'allogeneic effect' because B lymphocytes derived from F1 animals could cooperate with T lymphocytes derived from either parental strain; presumably, under these latter conditions, the interaction of parental strain T lymphocytes with F1 B lymphocytes would have been accompanied by as great an 'allogeneic effect' as that seen when T and B lymphocytes from MHC incompatible strains were used. Detailed genetic mapping studies demonstrated that the genes which controlled T lymphocyte/B lymphocyte interaction also mapped to the I-region of the MHC.

One of the major problems in the analysis of MHC restriction on T/B interaction resulted from the demonstration that macrophage/T lymphocyte interaction is restricted. It is therefore possible that the observed restriction on T/B interactions was secondary to a restriction on macrophage/T lymphocyte interaction which occurred early in the priming of the helper T lymphocyte. In order to resolve the issue of whether macrophage/T cell interaction controls the subsequent ability of primed T helper cells to interact with B cells, F1 T cells were primed *in vitro* with parental strain macrophages and then tested for their ability to collaborate with B cells syngeneic to the macrophage donor or with B cells derived from the other parental strain. Unfortunately, this experimental protocol resulted in conflicting results when performed in multiple independent laboratories. In some cases, restriction could only be observed at the level of macrophage/T cell interaction, with T/B interaction completely unrestricted, while in other studies clear-cut restrictions in both interactions were documented. The solution of this dilemma required the use of T cell clones and an in-depth analysis of the heterogeneity of the responding B cell population. Thus, there appear to be two distinct B

cell populations which are capable of interacting with primed T helper cells. One population can interact with histoincompatible helper T cells, requires only T cell-derived growth factors, high concentration of antigen, produces mainly IgM antibody, and does not require that the hapten and carrier be linked. In contrast, a second population of B cells requires genetically restricted T cell help, needs only low concentrations of antigen to differentiate into a plasma cell, produces mainly IgG antibody, and requires that the hapten and carrier molecules be linked.

CTL target cells

Following the demonstration of the requirements for MHC compatibility for macrophage/T lymphocyte interaction and for T lymphocyte/B lymphocyte interaction, it was shown by Zinkernagel and Doherty for virus-infected cells, by Shearer for targets modified with the TNP (trinitrophenyl) hapten, and by Bevan for targets bearing minor histocompatibility antigens, that the killing of antigen-bearing target cells by CD8⁺ T cells was also restricted by MHC antigens. In the virus studies, mice were infected with live virus and 7 days later their spleen cells were tested for their ability to kill virus-infected macrophages of the same or an allogeneic strain. T Cells derived from a virus-primed mouse would only kill target cells from the same strain and not allogeneic strains. In contrast to the results of studies with CD4⁺ helper or proliferating T cell populations, the restriction on the interaction of CD8⁺ CTLs with antigen-bearing target cells was mediated by the products of the K and D regions of the H2 complex (MHC class I antigens).

One of the original interpretations for the MHC restriction of macrophage/T lymphocyte and T/B lymphocyte interaction was that the interacting cells had to share a particular gene product (cell interaction model). This model was based on the idea that the interactions of immunocompetent cells involved like-like interactions and that the recognition of the specific antigen by the T cell receptor was independent of the molecules mediating cell-cell interaction. The results of their studies on the role of the MHC in restricting the interaction of CTLs with virus-infected targets led Zinkernagel and Doherty to propose an alternative model which stated that the antigen-specific T cell receptor was not specific for antigen, but recognized either modifications in the MHC class I antigens induced by viral proteins during the process of virus infection (altered self model) or that the nominal antigen formed a complex with the MHC antigens that was recognized as a unique

antigen by the T cell receptor (complex antigenic determinant model).

Studies with T cells from F1 animals formed the basis of support for these models which required the associative recognition of the nominal antigen and the MHC antigen. Thus, if F1 animals were immunized with a virus, the resultant virus-specific population of CTLs would lyse targets from either of the parental strains. However, if F1 T cells from a virally infected animal were transferred to one of the parental strains which was then infected with the virus, the resultant restimulated CTL population would only lyse target cells derived from the parental strain in which the T cells were boosted.

This experimental result is very difficult to reconcile with the cell interaction model, which states that a single F1 T cell would bear cell interaction molecules of both parental types and should, following boosting in one or the other parental strain environments, be capable of recognizing virus-infected targets derived from either parental strain. A much more likely explanation is that the F1 T cell population is composed of two distinct subpopulations, one of which is specific for viral determinants in association with MHC antigens of one parent, while the second is specific for viral determinants in association with MHC antigens from the other parent. Later studies demonstrated that CD4⁺ proliferating and helper T cells from F1 animals could also be divided into two distinct populations which were restricted in their interactions with macrophages or with B lymphocytes from one of the other parental strains, respectively.

The 1996 Nobel Prize in Physiology or Medicine was awarded to Peter Doherty and Rolf Zinkernagel 'for their discoveries concerning the specificity of the cell mediated immune defence'. These cellular studies formed the basis for the biochemical and molecular dissection of the polymorphism of MHC antigens which directly demonstrated that peptides derived from antigens are bound by the polymorphic regions of the MHC antigens and then displayed to the T cell receptor as a complex in the context of exposed sites on the α helices of the MHC molecules.

MHC restriction is learned in the thymus

It is now clear that the interaction of CD4⁺ T lymphocytes with either macrophages or B lymphocytes and the interaction of CD8⁺ CTLs with target cells involves co-recognition by a single T cell receptor of a complex of antigen and MHC class II molecules in the former case and a complex of antigen and MHC class I molecules in the latter case. The issue that must now be considered is whether this restriction is

created during the process of T cell differentiation in the thymus or whether the restriction is the result of priming to antigen in association with self MHC molecules in the periphery. This question has been resolved by the creation of chimeric animals in which F1 bone marrow cells are allowed to differentiate in lethally irradiated parental hosts. The results of these studies have demonstrated that CD8⁺ F1 T cells which develop in one parental environment are restricted to the recognition of antigen in association with MHC class I antigens of that parental strain. Similar studies with CD4⁺ T helper cells demonstrated that T cells from F1 to parent chimeras only possess the ability to cooperate with B cells and macrophages sharing MHC class II antigens with the MHC antigens of the parent used to construct the chimera. Thus, a contraction of the F1 T cell repertoire occurs during differentiation in the parental environment, as F1 bone marrow which differentiates under normal conditions in the F1 environment is capable of giving rise to T cells which can recognize antigen in association with MHC antigens expressed by either parental strain.

The critical host tissue that was responsible for inducing this restriction was shown to be the thymus and thymic epithelial cells were the critical cell type which determined MHC restriction. Additional support for this 'thymic selection' model for the generation of MHC restriction has been obtained from studies of mice bearing a transgenic T cell receptor. Mice bearing a T cell receptor from a CTL clone originally derived from a strain of mice of MHC type 'A' were crossed with different mouse strains either bearing MHC 'A' or not. Only those offspring bearing MHC 'A' had a large number of peripheral T cells expressing the transgenic T cell receptor, strongly suggesting that the recognition of MHC 'A' in the thymus during T cell differentiation was required for the expression of the transgenic TCR. The process of 'positive selection' involves the delivery of survival and differentiation signals to CD4⁺CD8⁺ thymocytes and is associated with commitments to the CD4⁺CD8⁻ and CD4⁻CD8⁺ lineages.

Collectively, these studies demonstrate that MHC restriction is an acquired or learned characteristic which occurs during T cell differentiation in the thymus in the absence of a foreign antigen. Following immunization of an animal, only those T cell clones specific for the foreign antigen and the learned MHC antigen are expanded. However, a number of studies have also demonstrated that a normal animal does contain T cells which recognize foreign antigens in association with MHC antigens not present in the

thymus during T cell differentiation. The thymic selection model can also accommodate this data if one integrates our understanding of the generation of MHC restriction with our concepts of why normal animals have high frequencies of T cells capable of recognizing alloantigens. All T cells are capable of recognizing foreign antigens in association with self MHC molecules and a certain fraction of these self-restricted T cell receptors (those responsible for alloreactivity) are also capable of recognizing foreign MHC antigens with their associated self peptides. It is therefore not surprising that the normal T cell repertoire can also contain some receptors capable of recognizing foreign antigenic peptides in association with foreign MHC antigens.

MICROBICIDAL MECHANISMS, OXYGEN-DEPENDENT

Seymour J Klebanoff, Department of Medicine, University of Washington, Seattle, Washington, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Phagocytes respond to stimulation with a burst of oxygen consumption, and much, if not all, of this extra oxygen consumed is converted to highly reactive oxidants which are toxic to ingested organisms and to certain extracellular targets. The stimulation may be physical, as when phagocytes adhere to a surface, or chemical, with a large variety of soluble or particulate agents being capable of initiating a respiratory burst. The particulate stimuli, as, for example, a microorganism, are generally coated with molecules such as products of the activation of complement (C3b or C3bi) and/or specific antibody which recognize receptors on the surface of the phagocyte. The soluble stimuli include phorbol esters, which are particularly potent, chemotactic factors such as the microbial product formyl-methionyl-leucyl-phenylalanine (fMLP), the complement activation product C5a, leukotriene LTB₄, certain lectins such as concanavalin A, lipopolysaccharide (LPS, endotoxin), certain cytokines as, for example, tumor necrosis factor α (TNF α , cachectin) and granulocyte-macrophage colony-stimulating factor (GM-CSF), as well as a number of other agents.

Physical and chemical stimuli, or two chemical stimuli, may combine to produce a stimulation which is greater than the additive effect of each alone. For example, many chemical stimuli increase the adherence of phagocytes through the increased surface expression of one or more members of a family of adherence glycoproteins (integrins) which consist of a variable α chain (CD11a, b or c) and a common β chain (CD18), thus amplifying the stimulation. TNF α , normally a weak stimulus, produces an amplified and prolonged stimulation of the respiratory burst when neutrophils are adherent to endothelial cells or a surface coated with serum or certain connective tissue proteins. Some chemical stimuli, for example LPS or interferon γ (IFN γ), while weak stimuli by themselves, can greatly increase the response of phagocytes to a number of second chemical stimuli. This process is termed priming.

The respiratory burst results from the assembly in the plasma membrane of a complex electron transport system which transfers electrons from NADPH on the cytoplasmic side of the membrane to oxygen in the extracellular fluid (or, when the plasma membrane is invaginated to form the phagosome, in the

intraphagosomal space) (Figure 1). This enzyme system has been called the phagocyte oxidase (phox) or the NADPH oxidase of phagocytes. Assembly occurs in part by incorporation of components present in cytoplasmic granules by a degranulation process, and in part by the translocation of cytosolic components.

Activation of the oxidase by intact cells is complex and incompletely understood; requirements differ to some degree with the nature of the stimulus. Stimulation is generally but not always initiated by the binding of the stimulant to specific high-affinity receptors on the surface of the cell. Examples include receptors for the Fc region of immunoglobulins and for complement products (C3b, C3bi) which recognize ligands on opsonized particles, the formyl peptide chemotactic receptor, etc. The mechanism of signal transduction following receptor-ligand interaction involves, for some stimuli, GTP-binding protein-induced activation of phospholipase C which hydrolyzes (poly)phosphatidylinositol releasing diacylglycerol and inositol 1,4,5-triphosphate (IP₃). Diacylglycerol activates cytosolic protein kinase C with translocation to the membrane and IP₃ can mediate Ca²⁺ mobilization from endoplasmic reticular stores. Phorbol esters, e.g. phorbol myristate acetate (PMA) or certain synthetic diacylglycerols, e.g. 1-oleoyl-2-acetyl-glycerol (OAG) bypass the early steps of signal transduction to activate protein kinase C directly. Activation of cyclic AMP-dependent protein kinase (protein kinase A) or tyrosine kinase also may occur. As a result of protein kinase activation, a component (or components) of the oxidase is phosphorylated.

As a consequence of stimulation, at least three cytosolic components of the oxidase, p47^{phox}, p67^{phox}, and p21^{rac} are translocated to the plasma membrane where they combine with a unique membrane-associated cytochrome *b* to form the active NADPH oxidase. An intracellular pool of the cytochrome *b* is present in the membranes of the specific (secondary) granules of neutrophils and is incorporated into the oxidase complex when the membrane of the granule fuses with the plasma membrane following stimulation. The cytochrome *b* is a heterodimer composed of a small 22 kDa α subunit (p22^{phox}) tightly linked noncovalently to a heavily glycosylated large 91 kDa β subunit (gp91^{phox}).

Figure 1 Oxygen-dependent antimicrobial systems of phagocytes.

gp91^{phox} has a transmembrane configuration with the C-terminus extending into the cytoplasm and the glycosylated portion extending into the extracellular (or intraphagosomal) space. The cytochrome contains two heme groups and flavin adenine dinucleotide (FAD) and has a characteristic absorption peak at 558 nm (and thus the name flavocytochrome *b*₅₅₈). Flavocytochrome *b*₅₅₈ contains both NADPH- and FAD-binding sites in the C-terminal third of the gp91^{phox} subunit which extends into the cytoplasm and has an unusually low midpoint potential (-245 mV) which allows it to directly reduce oxygen, suggesting that flavocytochrome *b*₅₅₈ contains all of the elements necessary for the transfer of electrons from NADPH through FAD to oxygen. The gene for the β subunit is located at position Xp91.1 on the short arm of the X chromosome and is expressed only in myeloid cells. It encodes a 65 kDa polypeptide which contains a number of N-linked glycosylation sites. The gene for the α subunit is autosomal in location and is expressed in a wide variety of cells. Flavocytochrome *b*₅₅₈ is associated in the membrane with a low molecular weight GTP-binding protein Rap1A with unknown function.

The cytoplasmic components of the oxidase appear to be regulatory molecules acting on flavocytochrome *b*₅₅₈ to convert it from a dormant to an enzymatically active NADPH oxidase. p47^{phox} and p67^{phox} exist in the cytoplasm as a complex in association with a 40 kDa protein, p40^{phox}, of unknown function. p47^{phox} is a 47 kDa cationic protein with several serine phosphorylation sites. Its

phosphorylation at multiple sites is required for translocation to the membrane. Binding of the 67 kDa cytosolic component (p67^{phox}) is dependent on prior translocation of p47^{phox}. p21^{rac} is a member of the *rho* class of *ras*-related small GTP-binding proteins which is present in the cytoplasm as a complex with an inhibitory molecule, GDP dissociation inhibitor or *rho* GDI which maintains *rac* in an inactive GDP-bound state. Activation of the oxidase is associated with the dissociation of the *rac*-*rho* GDI complex with the release of an active GTP-bound *rac* which migrates to the membrane. There are two highly homologous forms of *rac* (*rac1* and *rac2*), with *rac1* reported to be the regulatory component of the guinea pig macrophage NADPH oxidase and *rac2* serving the same function in the human neutrophil oxidase. p47^{phox}, p67^{phox} and p40^{phox} contain domains homologous to a noncatalytic region of *src* tyrosine kinase (*src* homology 3 or SH3 domain) which binds to proline-rich sequences mediating the protein-protein binding required for the association of p47^{phox} and p67^{phox} with each other, with p40^{phox} and with flavocytochrome *b*₅₅₈. The activated oxidase is associated with submembranous cytoskeletal components.

In cell-free preparations of phagocytes, activation of the NADPH oxidase can be achieved by the addition of an anionic detergent such as arachidonic acid, sodium dodecyl sulfate or other *cis* unsaturated fatty acids. Under these conditions, NADPH oxidase activity requires NADPH, oxygen, a cell membrane fraction, a cytosolic fraction, Mg²⁺, GTP, and under

some conditions, ATP. Reconstitution of the phagocyte NADPH oxidase has been achieved with recombinant flavocytochrome b_{558} , p47^{phox}, p67^{phox} and p21^{rac}.

Chronic granulomatous disease (CGD) is an inherited disease characterized by repeated and severe infections with pyogenic organisms. It is associated with a phagocytic cell microbicidal defect in which some microorganisms are ingested normally but are not killed, due to a defect in the respiratory burst oxidase. CGD can result from different genetic lesions affecting one or another of the components of the oxidase. The majority of patients with CGD (56%) have X-linked inheritance and almost all of these patients lack spectroscopic evidence of flavocytochrome b_{558} . Although the primary lesion is in the gene encoding for the β chain, both the α and β chains of cytochrome b_{558} are absent, indicating that the β chain is required for the stable expression of the α chain. In rare cases of X-linked CGD, cytochrome b_{558} is present in normal amounts, but has a single Pro-His substitution at residue 415 of the 91 kDa subunit, which renders the oxidase non-functional. The remaining CGD patients (44%) exhibit autosomal recessive inheritance. The phagocytes of most of these patients contain normal levels of cytochrome b_{558} but lack either p47^{phox} or, less frequently, p67^{phox}. Rare autosomal recessive CGD patients lack cytochrome b_{558} , probably due to a defect in the 22 kDa cytochrome b_{558} subunit. The addition of IFN γ to neutrophils or monocytes from selected CGD patients *in vitro* or the subcutaneous injection of IFN γ into some CGD patients results in a partial correction of the metabolic and microbicidal defect. Gene therapy, in which the appropriate normal gene is introduced into defective cells, is under study.

The initial product of the respiratory burst is the superoxide anion (O_2^-), which exists in equilibrium with the perhydroxyl radical (HO_2), with a pK_a of 4.8. O_2^- is predominantly a reductant, but also can act as an oxidant. Since many biologically important compounds react rather sluggishly with O_2^- , it has been proposed that O_2^- does not have the necessary reactivity to be directly toxic to cells. However, the chemical reactivity of O_2^- is increased considerably in a nonpolar environment, as in the hydrophobic region of membranes where the reactions of O_2^- are not in competition with the proton requiring dismutation reaction. Further, HO_2 is a considerably stronger oxidant than is O_2^- , raising the possibility that a localized fall in pH as might occur in a phagosome or at a membrane surface would cause a shift in the $O_2^- \rightleftharpoons HO_2$ equilibrium toward the more potent protonated form. Finally, the relatively low reactivity

of O_2^- may allow it to diffuse through biologic fluids and the anion channels of certain membranes to be toxic at a distance through the formation of more reactive oxidants.

When two molecules of O_2^- interact, one is oxidized and the other reduced in a dismutation reaction with the formation of H_2O_2 .

This reaction occurs either spontaneously or catalyzed by superoxide dismutase (SOD). Spontaneous dismutation is optimal at pH 4.8 and falls as the pH increases where catalysis by SOD becomes more significant. Although an early rise in intraphagosomal pH has been reported, most studies have indicated that the pH within the phagosome falls to levels where spontaneous dismutation is rapid, suggesting that catalysis by SOD may be unnecessary for H_2O_2 formation. There is no evidence that leukocytic SOD is released into the phagosome; SOD, however, can be introduced there as a component of the ingested organism. Although H_2O_2 formed by phagocytes has toxic properties, its reactivity is relatively low when compared to toxic products formed from it, such as hypohalous acids and hydroxyl radicals ($OH^\cdot$).

The toxicity of H_2O_2 is greatly increased by reaction with peroxidase and a halide. There are a number of distinct peroxidases in mammalian tissues which differ in their primary structure, heme prosthetic group, and in the halide requirement for microbicidal activity. The peroxidase of neutrophils and monocytes (myeloperoxidase, MPO) is present in a subpopulation of cytoplasmic granules (azurophil or primary granules) and is discharged into the phagosome by the degranulation process which follows the phagocytosis of microorganisms or other particles. Although the MPO-mediated antimicrobial system is effective with chloride, bromide, iodide and the pseudohalide thiocyanate, the physiologic halide is chloride. MPO reacts with H_2O_2 generated either by the respiratory burst or certain ingested microorganisms, to form a complex (compound I) which oxidizes chloride to hypochlorous acid ($HOCl$) (Figure 2). Compound II is an inactive form of peroxidase formed by an excess of H_2O_2 . O_2^- can reduce compound II back to the active peroxidase with restoration of activity and may function in this way in the phagosome. O_2^- also reacts with MPO to form compound III (oxypoxidase) which can decay to MPO, be converted to compound II by H_2O_2 or be catalytically active. $HOCl$ is in equilibrium with its ionized form hypochlorite (OCl^-) with a pK_a of 7.3 and, at acid pH, $HOCl$ can react with excess chloride to form

Figure 2 MPO complex formation. MPO forms three complexes: compounds I, II and III. O_2^- can influence the reactivity of MPO by: 1) forming H_2O_2 by dismutation which reacts with MPO to form compound I, 2) reacting with MPO to form compound III, and 3) converting the inactive compound II to native MPO. chlorine. These are powerful oxidants which are highly toxic to microorganisms. Hypochlorous acid can react with certain nitrogen-containing compounds to form monochloramines and dichloramines with retention of some oxidizing activity and toxicity.

In addition to its toxicity to a variety of intraphagosomal targets (e.g. bacteria, fungi, protozoa), the MPO system can be released to the outside of the cell, to be toxic to adjacent microorganisms (bacteria, fungi, viruses, protozoa, helminths), and normal and malignant mammalian cells, and to inactivate certain extracellular substances, e.g. $\alpha 1$ -proteinase inhibitor, leukotrienes and chemotactic factors. Although the peroxidase system is generally inhibitory in nature, it can stimulate certain cells to exhibit their secretory functions (platelets, mast cells) and can activate certain enzymes (procollagenase, progelatinase) through its oxidative action.

When monocytes mature into macrophages, either *in vitro* or *in vivo*, they lose their granule peroxidase. The respiratory burst also is markedly depressed and, as a result, a number of ingested organisms can survive and replicate, producing disease. Activation of the macrophage by $IFN\gamma$ or certain other cytokines partially restores the respiratory burst and cidal activity.

Eosinophil peroxidase (EPO), which is present in the matrix of the cytoplasmic granules of eosinophils, can utilize chloride, but less efficiently than MPO. Bromide appears to be the physiologic halide

for the peroxidase- H_2O_2 -halide system in this cell type and the product of its oxidation, hypobromous acid, like HOCl, has broad reactivity. Thiocyanate also has been reported to function with EPO. MPO and particularly EPO are strongly basic proteins which can bind to the target by ionic bonds and in this way be carried into phagocytes which lack a granule peroxidase (e.g. macrophages).

Lactoperoxidase (LPO) cannot oxidize chloride and appears to utilize thiocyanate in an antimicrobial system in milk and saliva. The source of H_2O_2 may be microbial metabolism, adjacent phagocytes or soluble enzyme systems such as xanthine oxidase in milk. Hypothiocyanous acid is the toxic species formed.

The oxidants formed by the peroxidase system can oxidize the target cell or molecule at a variety of chemical sites (sulfhydryl groups, iron-sulfur centers, sulfur-ether groups, unsaturated fatty acids, terminal amino groups, peptide bonds, etc.) and the binding of the halide in covalent linkage to the target (halogenation) also occurs. The nature of the lesion which causes cell death is not known; perhaps no single lethal lesion will be found.

A number of lines of evidence suggest an important role for peroxidase-derived oxidants in the toxic activity of phagocytes.

1. MPO, H_2O_2 and a halide form a highly toxic system.
2. MPO is released and H_2O_2 is formed by stimulated neutrophils, and chloride is present in adequate amounts. MPO and H_2O_2 and the products of halide oxidation can be detected in the phagosome.
3. A high proportion of the oxygen consumed by stimulated neutrophils can be accounted for by the formation of HOCl.
4. A role for H_2O_2 in the toxic activity of neutrophils is suggested by the protective effect of catalase and by the partial reversal of the microbicidal defect in CGD neutrophils by H_2O_2 .
5. The requirement for MPO for optimum microbicidal activity is suggested: a) by the decrease in the microbicidal activity of normal neutrophils by certain peroxidase inhibitors; b) by the defective microbicidal activity of neutrophil cytoplasts (which lack nuclei and are greatly depleted of granules and thus MPO, but have an intact respiratory burst), unless MPO is added; and c) by the microbicidal defect in neutrophils from patients with hereditary MPO deficiency, which lack MPO. The microbicidal defect is not as severe as in CGD, and most (but not all)

patients are clinically well. In contrast to CGD, the respiratory burst in MPO deficiency is greater than normal. Thus, the increased accumulation of nonperoxidase-derived oxidants may compensate in part for the loss of MPO in microbicidal activity.

A second mechanism by which the toxicity of H_2O_2 is increased is by its reduction to hydroxyl radicals ($\text{OH}^\cdot$). H_2O_2 reacts with Fe^{2+} (Fenton's reagent), or another trace metal, to form $\text{OH}^\cdot$ as follows:

When the iron concentration is limiting, the reduction of the Fe^{3+} formed is required for the continued formation of $\text{OH}^\cdot$. This can be accomplished by O_2^- (as well as certain other reducing agents) as follows:

with the overall reaction being:

which has been called the iron-catalyzed Haber-Weiss reaction, or the superoxide-driven Fenton reaction.

The Haber-Weiss reaction is limited by the very low solubility of Fe^{3+} due to the formation of polynuclear hydrated iron complexes. Certain iron chelators can maintain Fe^{3+} in solution, and when there is the retention of an iron aquo-coordination site which can be oxidized and reduced, the complexed iron remains catalytically active in the Haber-Weiss reaction. The chelator, for example, ethylenediamine tetraacetic acid (EDTA), is thus stimulatory. Other chelators, e.g. deferoxamine, bind to all six coordination sites of iron, displacing water. These complexes are catalytically inactive and the chelator thus inhibits the Haber-Weiss reaction. A biologically relevant chelator which facilitates the iron-catalyzed Haber-Weiss reaction has been sought. Lactoferrin or transferrin are stimulatory when fully saturated with iron, but are inhibitory when unsaturated or partially saturated (their natural state). Other chelators reported in some studies to facilitate iron-dependent $\text{OH}^\cdot$ formation include ferritin, phosphate, phosphonucleotides, DNA, and α -picolinic acid. When the pH falls, the solubility of Fe^{3+} increases, and under these conditions (which may exist in the phagosome), the formation of $\text{OH}^\cdot$ may not require a chelator.

O_2^- and H_2O_2 are formed in large amounts by

stimulated phagocytes, and it might be anticipated therefore that $\text{OH}^\cdot$ generation by the Haber-Weiss reaction would occur. However, the formation of $\text{OH}^\cdot$ by phagocytes remains controversial. The presence of free iron appears to be the limiting factor in phagocytes, since only a small amount of $\text{OH}^\cdot$ was detected by electron paramagnetic resonance (EPR) spectroscopy unless iron was added. Both the chelating effect of released lactoferrin, and the scavenging of H_2O_2 by myeloperoxidase decrease the formation of $\text{OH}^\cdot$ by neutrophils. Potential sources of iron include iron released from the ingested organism or from iron transport or storage proteins. As a result of its high reactivity, $\text{OH}^\cdot$ is readily scavenged and thus must be formed in close proximity to its target site. H_2O_2 released by phagocytes can, however, move to distant sites where reaction with local iron may produce damage.

Recently it has been proposed that $\text{OH}^\cdot$ is formed in small amounts by stimulated neutrophils by an MPO-dependent mechanism as follows:

MPO catalyzes the H_2O_2 -dependent formation of HOCl which reacts with O_2^- to form $\text{OH}^\cdot$.

Singlet oxygen ($^1\text{O}_2$) is formed when an unpaired valence electron of oxygen is raised to an orbital of higher energy with an inversion of spin. There are two forms of $^1\text{O}_2$, delta and sigma. Delta $^1\text{O}_2$, while having a lower energy above ground state than sigma $^1\text{O}_2$, has a considerably longer lifespan (approximately 2 μs) and is the reactive form of $^1\text{O}_2$ in solution. It is a strong electrophile which reacts with compounds in areas of high electron density to form oxygenated products. A well-established mechanism for the formation of $^1\text{O}_2$ is by reaction of H_2O_2 with OCl^- . Since both reactants are formed by neutrophils their interaction to form $^1\text{O}_2$ has been proposed as follows:

↓

The formation of $^1\text{O}_2$ by the spontaneous dismutation of O_2^- and by the Haber-Weiss reaction also

has been proposed. However, attempts to demonstrate 1O_2 formation by intact neutrophils have been controversial. It is unclear whether 1O_2 is formed in amounts sufficient to contribute significantly to the antimicrobial effect.

Murine macrophages can be induced by a number of cytokines to form nitric oxide ($NO^\cdot$). A cytosolic nitric oxide synthase is formed in these cells which, in the presence of NADPH, tetrahydrobiopterin and oxygen, oxidizes the guanidino nitrogen of L-arginine to form L-citrulline and $NO^\cdot$. $NO^\cdot$ can react with O_2^- to form the peroxynitrite ion ($ONOO^-$) which, when protonated, decomposes to form a strong oxidant with the properties of $OH^\cdot$. Ultimately, nitrite and nitrate are formed. $NO^\cdot$ can oxidize iron-sulfur centers of proteins with resultant iron loss and the peroxynitrite ion is a potent oxidant of sulfhydryl groups. Although the formation of $NO^\cdot$ and its involvement in the microbicidal and cytotoxic activity of murine phagocytes has been widely reported, its formation and role in human phagocytes has been controversial.

Microorganisms and mammalian cells, including phagocytes, can be protected from the oxidants formed by stimulated phagocytes by a number of mechanisms (Figure 3). Sensitivity to H_2O_2 correlates with the level of the H_2O_2 -scavenging enzymes catalase and glutathione peroxidase. Glutathione oxidized by glutathione peroxidase is reduced by glutathione

reductase and NADPH generated by the hexose monophosphate shunt which serves to dissipate excess H_2O_2 . Sensitivity to O_2^- and to oxidants dependent on O_2^- for their formation is affected by SOD levels and taurine or similar scavengers may neutralize the toxicity of $HOCl$ or other halide oxidation products formed by the peroxidase system.

In summary, phagocytes produce a number of reactive oxygen species on stimulation. Some, e.g. $HOCl$ or $OH^\cdot$ are labile oxidants which are highly reactive but short-lived and function under conditions in which diffusion distances are short, and protein and other scavengers are excluded, such as in the phagosome, or when the phagocyte is adherent to an antibody and/or complement-coated surface. Others, e.g. H_2O_2 or chloramines, are less reactive but more stable, and can penetrate into biological fluids rich in proteins and other scavengers, or across membranes, to be toxic at a distance under conditions in which the labile oxidants are readily scavenged. These agents, acting alone or synergistically with proteinases or granule basic proteins, contribute, along with oxygen-independent mechanisms, to the toxic effects of phagocytes.

MICROBICIDAL MECHANISMS, OXYGEN-INDEPENDENT

Robert I Lehrer, Section of Molecular Host Defense, Department of Medicine, UCLA School of Medicine, Los Angeles, California, USA

Historical background

The ability of certain leukocytes to ingest and kill microorganisms was established over a century ago by Eli Metchnikoff, a comparative zoologist who coined the terms 'phagocytosis' and 'phagocyte'. Metchnikoff had recognized the central importance of phagocytosis in host defense and vigorously proselytized the community of fin-de-siècle protoimmunologists on its behalf. In 1891, Hankin reported 'it is possible to obtain from cells that are or can become phagocytes a substance having bacteria-killing powers'. Many investigators attempted to define this substance in the ensuing years. Although the rudimentary technology available for protein purification generally restricted the success of early efforts, it did not preclude the creation of memorable names, such as 'leukins' and 'phagocytin', to describe these uncharacterized molecules. With the exception of the noteworthy discovery of lysozyme by Sir Alexander Fleming in 1922, the modern delineation of oxygen-independent microbicidal mechanisms began in the 1960s when Zeya and Spitznagel reported that rabbit and guinea pig neutrophils contained a group of relatively small 'lysosomal cationic proteins' that exhibited a broad spectrum of antimicrobial activity *in vitro*. Although the significance of this discovery was overshadowed by the concomitant delineation of oxidative microbicidal mechanisms in phagocytes and by the delay in finding the human counterparts of these peptides ('defensins'), interest in the endogenous antimicrobial molecules of phagocytes has increased sharply during the past few years. Because much of the available information about nonoxidative ('oxygen-independent') mechanisms was derived from work on human neutrophils, these cells will be a principal focus of this section. More recently, antimicrobial peptides and proteins have been demonstrated in epithelial cells and secretory glands of the genitourinary, respiratory and digestive tracts, suggesting that such molecules play important roles in defending moist, mucosal surfaces throughout the body.

Neutrophils

Neutrophils (PMNs) are short-lived, highly mobile phagocytes that can ingest bacteria or fungi and kill

them by a variety of oxidative and nonoxidative mechanisms. The oxidative mechanisms, which are described in a separate entry, are mediated by molecules whose formation requires superoxide or hydrogen peroxide. In human neutrophils, the antimicrobial oxidants are believed to include hydroxyl radicals, hypochlorous acid and chloramines. In some species, PMNs and macrophages can also form reactive oxides of nitrogen that possess antimicrobial properties. The nonoxidative mechanisms of neutrophils are mediated, in large part, by potent antimicrobial polypeptides, most of which reside within the cell's numerous cytoplasmic granules. Acting conjointly with the neutrophil's oxidants, these endogenous antibiotics may be delivered directly to microbes sequestered within phagocytic vacuoles or they may be secreted outside the neutrophil to inactivate extracellular microbes. Microorganisms isolated within phagocytic vacuoles can also be deprived of nutrients, subjected to harsh and unfavorable ionic conditions and low pH, and exposed to potentially noxious surfactants, such as lysolipids. Because the principal peptide antibiotics in human azurophil granules typically exist in concentrations of 1–5 μg per 10^6 PMNs, fusion of only 1% of these granules to a phagosome 1 μm in diameter may result in intraphagosomal concentrations as high as 20–100 mg ml^{-1} for *each* antimicrobial polypeptide. Under such conditions, interactions and reactions may occur that are not readily predictable from information derived from test-tube experiments.

Approximately a third of the 4500 granules in the cytoplasm of a typical mature human PMN contain myeloperoxidase, and are referred to as 'primary' or 'azurophil' granules. These granules contain most of the PMN's nonoxidative antimicrobial effectors, including defensins, cathepsin G, azurocidin and bactericidal/permeability increasing factor (BPI). The neutrophil's peroxidase-negative granule populations contain the majority of its lysozyme (muramidase), as well as other antimicrobial molecules, such as the α -helical peptide known either as 'FALL-39' or 'hCAP-18' and a 14 kDa secretory phospholipase A_2 .

Because azurophil granules are lysosome-like, their internal contents probably remain inert as long as the surrounding granule membrane remains intact. Degranulation, the fusion of granules with the

peripheral or perivacuolar plasma membrane, can insert granule membrane contents into the cell's or phagosome's membrane and delivers the granule's antimicrobial contents into the extracellular or phagosomal compartments. In contrast to macrophages, the human neutrophil's phagocytic vacuoles are not as strongly acidic. Studies with fluorescent pH probes indicate that newly formed neutrophil phagosomes are neutral to mildly alkaline for 15–45 minutes, with subsequent acidification to approximately pH 6.0. Initial vacuolar alkalization and the respiratory burst are linked temporally and perhaps mechanistically.

Calprotectin

The cytoplasm of human neutrophils contains remarkably high concentrations of 'calprotectin', a member of the widespread S-100 protein family. Human neutrophil calprotectin is a heteropolymer, composed of light (MRP8) and heavy (MRP14) chains. It constitutes over half of the total cytosolic protein present in human neutrophils. Although calprotectin is not secreted from intact neutrophils, its release from dead and dying neutrophils creates high concentrations of the protein in pus or abscess fluids, which also contain large amounts of neutrophil-derived antimicrobial peptides and proteins as well as microbicidal nucleohistones and histone fragments.

Calprotectin has also been called 'L1 protein', 'calgranulins A and B' or 'MRP8/MRP14'. In addition to neutrophils, it is also found in reactive tissue macrophages, in nonkeratinizing squamous epithelia and in reactive epidermal cells. The C-terminal portion of calprotectin's heavy chain, MRP14, contains a sequence identical to a peptide originally described as a neutrophil immobilizing factor, 'NIF'. Calprotectin concentrations of 50–250 $\mu\text{g ml}^{-1}$ inhibit growth by *Staphylococcus aureus*, *Staph. epidermidis* and *Escherichia coli*, and lower concentrations (4–32 $\mu\text{g ml}^{-1}$) inhibit growth by *Candida albicans*, possibly by depriving the *Candida* cells of zinc. Calprotectin purified from rat inflammatory peritoneal cells was markedly cytotoxic for mitogen-stimulated lymphocytes and various tumor cell lines, in which it induced apoptosis. It is likely that calprotectin protects neutrophils, and the other cells that express it, against microbes that invade the host cell's cytoplasm directly or by lysing phagosomal membranes.

Defensins

Classical alpha (α)-defensins are small, cysteine- and arginine-rich antimicrobial peptides with a mass of

3.5–4.0 kDa. They contain 29–34 amino acid residues, including six invariant cysteines that form three intramolecular disulfide bonds. Slightly larger antimicrobial peptides, now called beta (β)-defensins, were discovered somewhat later in the epithelial cells that line the bovine trachea and tongue and in avian and bovine neutrophils. In humans, a β -defensin (hBD-1) is produced by cells in the kidney, male and female genitourinary tracts, trachea and small airways, placenta, pancreas and salivary glands. hBD-1 is not produced by neutrophils or other cells derived from the bone marrow. Individual defensin molecules have a triple-stranded β -sheet structure and form dimers with six-stranded β sheets. Assembly of defensins into multimeric structures may be necessary for them to exert their antimicrobial and membrane-perturbing effects.

Defensin genes show extraordinary multiplicity and provide compelling evidence of the rapid evolution of the sequences that encode the mature defensin peptide. The genes for human α - and β -defensin lie within 150 kb of each other on the short arm of chromosome 8. This observation, and other recent studies suggest that α - and β -defensins arose, via multiple gene reduplications and mutations, from a common gene existent in a progenitor common to birds and mammals. Myeloid α -defensin genes contain three exons, whereas enteric α -defensin genes contain only two. The primary structures of several α - and β -defensins are shown in Figure 1.

Defensins are synthesized as 93–100 amino acid long, nonglycosylated prepropeptides. The amino acids destined to form the mature defensin peptides constitute the C-terminal portion of their respective precursors. After cotranslational removal of a highly conserved 19 residue signal sequence, the resulting prodefensin undergoes sequential proteolytic cleavages that yield the mature defensin molecules that are stored within the neutrophil's azurophil granules. The defensin propeptide is polyanionic and may protect defensin-producing cells from autocytotoxicity. It also plays a key role in the intracellular trafficking that targets defensins to the azurophil granule compartment of the neutrophil.

Since the first description of 'lysosomal cationic proteins' in rabbit and guinea pig neutrophils, more than 50 different α -defensins and 20 different β -defensins obtained from avian and mammalian sources have been identified and sequenced. Although α -defensins are exceptionally abundant constituents of human, rabbit, guinea pig and rat neutrophils, they are not found in those of mice, horses, pigs or cattle. Human neutrophils contain four defensins, called HNP-1, -2, -3 and -4 (Figure 1). α -Defensins constitute 5–7% of the total cellular

Figure 1 Sequences of selected defensins. α -Defensins HNP-1, -2, -3, and -4 (human neutrophils) and HD-5 and -6 (human small intestinal Paneth cells) are α -defensins. TAP (tracheal antimicrobial peptide) and Gal-1 (gallinacin-1) are present in bovine tracheal epithelial cells and chicken leukocytes, respectively. hBD-1, a human β -defensin, is found in many human epithelial cells and secretory tissues. Amino acids are shown in standard single letter code: A, alanine; C, cysteine; D, aspartic acid; E, glutamic acid; F, phenylalanine; H, histidine; I, isoleucine; K, lysine; L, leucine; M, methionine; N, asparagine; P, proline; Q, glutamine; R, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine. Conserved cysteine and glycine residues are boxed, and dashes (gaps) have been introduced in the actual sequences to maximize the alignment between α - and β -defensins. The lines above the sequences show the slightly different cysteine disulfide pairing patterns found in α - and β -defensins.

protein of human neutrophils and 30–50% of their azurophil granule protein, but are absent from human monocytes, lymphocytes, lung macrophages and eosinophils.

Two additional α -defensins, HD-5 and HD-6 (Figure 1), are produced by the small intestinal Paneth cells of humans. These secretory and phagocytic cells line the base of the small intestine's crypts, just below the mitotic zones that are responsible for replenishing effete intestinal epithelial cells. Paneth cells also contain lysozyme and type 2 phospholipase A₂. The mixture of intestinal defensins, lysozyme and phospholipase A₂ that Paneth cells secrete undoubtedly constitutes a formidable barrier to microbes attempting to invade intestinal crypts.

Both α - and β -defensins kill many gram-positive bacteria, gram-negative bacteria and fungi *in vitro*. Several α -defensins can also inactivate herpes simplex and other enveloped viruses. The microbicidal activity of defensins towards many fungi and gram-negative bacteria is inhibited by divalent cations and by the NaCl concentrations found in extracellular fluids. Their activity against gram-positive bacteria is less affected by their ionic environment. Human neutrophil defensins act most efficiently against metabolically active microbial targets, whereas the more cationic defensins of rabbit or rat neutrophils can also kill quiescent, stationary-phase microorganisms. Consequently, human defensins manifest optimal bactericidal activity when the targets are provided with nutrients, such as glucose for *Staph.*

aureus or more complete media for most *E. coli* strains.

Human defensins form voltage-regulated ion channels in artificial 'black-lipid' membrane bilayers and they sequentially permeabilize the outer and inner membranes of metabolically active *E. coli*. Their requirement for active microbial metabolism implicates the participation of the target cell's transmembrane electromotive force in defensin-mediated antimicrobial activity. The bacterial gene (*phoP*), essential for mouse virulence by *Salmonella typhimurium*, also influences the organism's susceptibility to defensins.

Defensins can be cytotoxic to mammalian cells in culture, and this property may be involved in inflammatory processes or antineoplastic defenses. The cytotoxic potential of defensins is mitigated by the presence of serum, which contains several proteins that bind defensins, including α_2 -macroglobulin, α_1 -antitrypsin, α_1 -antichymotrypsin, antithrombin 3 and antiplasmin. Some defensins cause the degranulation of mast cells *in vitro* and many can inhibit protein kinase C and other kinases. Human defensins HNP-1 and HNP-2 are potent and selective stimuli for chemotaxis by mononuclear cells (T lymphocytes and monocytes), hence their extracellular release may promote the recruitment of these cells into inflamed or infected lesions *in vivo*. Low concentrations of defensins were reported to enhance fibroblast and epithelial cell growth *in vitro*, suggesting that defensins might promote tissue repair and

regeneration *in vivo*. Certain α -defensins, most notably rabbit defensin NP-3a (also called 'corticostatin'), bind reversibly to the adrenocorticotropin hormone (ACTH) receptor of adrenal cortical cells and competitively inhibit ACTH binding.

Bactericidal/permeability increasing proteins (BPI)

BPI is a 55–60 kDa, lysine-rich azurophil granule protein that accounts for less than 1% of total human PMN protein. BPI binds to bacterial lipopolysaccharide (LPS) with high affinity, and can mitigate several potentially toxic effects of LPS *in vitro*. Although BPI is bactericidal for rough gram-negative bacteria, including *E. coli* and *S. typhimurium*, it lacks activity against gram-positive bacteria and fungi. BPI exerts maximal bactericidal activity at neutral pH, is relatively insensitive to ionic strength, but is inhibited by millimolar concentrations of calcium or magnesium ions.

The molecular organization of BPI includes an antibacterial N-terminal domain that is both highly cationic and amphiphilic in nature, and a slightly acidic C-terminal domain that contains three hydrophobic regions which might anchor BPI to the azurophil granule membrane and prevent its external secretion. These domains are separated by a hydrophilic and proline-rich region which may serve as a hinge. BPI was reported to bind rapidly to the outer membrane of susceptible gram-negative bacteria and to cause increased outer membrane permeability to hydrophobic molecules and selective activation of enzymes that degrade envelope phospholipids and peptidoglycans. More recently, BPI was also shown to affect the integrity of the inner bacterial membrane.

BPI shows substantial homology to LBP, a lipopolysaccharide-binding protein that is synthesized by hepatocytes and circulates as an acute phase reactant in the plasma of humans and animals. BPI and LBP share the ability to bind the lipid A region of LPS and are immunologically cross-reactive; however, LBP lacks bactericidal activity. The genes for BPI and LBP are located in the same region of the long arm of chromosome 20.

Autoantibodies to BPI are commonly present in the serum of patients with inflammatory bowel disease or primary sclerosing cholangitis, a disorder of small bile ducts. What role, if any, these antibodies play in the pathogenesis of these disorders is unknown.

Type II phospholipase A₂

By definition, phospholipase A₂ (PLA₂) is an enzyme that can remove fatty acids from the middle (*sn*-2) carbon atom of phosphoglycerides. Although several different phospholipase A₂ enzymes occur in mammalian cells, only one of these – a 14 kDa type 2 PLA₂ that is also called secretory PLA₂ (sPLA₂) – has potent microbicidal properties. sPLA₂ differs substantially from the type 1 PLA₂ found in pancreatic secretions, both in its preference for phospholipid substrates such as phosphatidylethanolamine, which are prominent in bacterial membranes, over phosphatidylcholine, and in significant aspects of its primary structure.

sPLA₂ is present in secretory (nonazurophil) granules of human neutrophils and in the secretory granules of small intestinal Paneth cells. The entry of sPLA₂ into the neutrophil's phagocytic vacuoles has been demonstrated by immunoelectron microscopy. sPLA₂ is secreted extracellularly from neutrophils exposed to secretagogues, such as phorbol esters or calcium ionophore, and by Paneth cells exposed to bethanecol (a parasympathomimetic agonist), bacteria or LPS. Serum sPLA₂ is greatly elevated in patients with bacterial infections or sepsis, and rises sharply within 3 hours of the experimental administration of LPS to uninfected patients. High concentrations of sPLA₂ are also present in human tears.

Serine proteases and their congeners

Human PMN granules contain several neutral proteases, and congeners that manifest microbicidal activity *in vitro*. The most prominent of these are cathepsin G (a chymotrypsin-like enzyme), elastase and an enzymatically-inactive elastase congener, 'azurocidin'. It has been suggested that translocation of serine proteases to the external surface of activated neutrophils, where they are unaffected by protease inhibitors, may facilitate chemotaxis and their ability to exit the vascular compartment and enter sites of inflammation. Neutrophils of patients with Chédiak-Higashi syndrome contain greatly reduced amounts of both cathepsin G and elastase, deficiencies that may contribute to their impaired bactericidal performance *in vitro* and to the frequent infections sustained by these patients *in vivo*.

Cathepsin G is a 27 kDa, variably glycosylated cationic protein that is found in the azurophil granules of human PMNs. It also occurs, but in much smaller amounts, in human blood monocytes. The five exon cathepsin G gene is located on chromosome 14, adjacent to the genes for lymphocyte granzymes B and H and mast cell chymase 1. Cathepsin G kills

gram-positive and gram-negative bacteria as well as certain fungi, and is especially effective against *Neisseria gonorrhoeae*. The bactericidal activity of purified cathepsin G is inhibited by increasing ionic strength or serum concentration. Enzymatically-inactive cathepsin G retains bactericidal and fungicidal activity.

The human neutrophil elastase gene also has five exons, but is located on the short arm of chromosome 19, extremely close to genes for azurocidin, proteinase 3 and granzymes A, B, H and M. Human neutrophil elastase exists as a mixture of four isoenzymes that differ only in their carbohydrate content. Elastase can degrade bacterial cell wall protein, potentiate the bacteriolytic activity of lysozyme, and potentiate the microbicidal activity of cathepsin G *in vitro* by a nonenzymatic mechanism. Theoretically, it might also cleave the antimicrobial 25 kDa N-terminal portion of BPI from the intact holoprotein molecule and participate in trimming the cathelin domain from hCAP-18/FALL-39 to generate the antimicrobial peptide it carries. Weak intrinsic antibacterial activity of elastase has been demonstrated towards the gram-negative bacterium *Acinetobacter* 199 A, but detailed studies with other bacteria have not been reported.

Azurocidin (also called CAP-37) is a 29 kDa protein that shares considerable N-terminal sequence homology with the human neutrophil's elastase and cathepsin G. Because it contains glycine instead of serine at the expected catalytic site, azurocidin lacks protease and peptidase activity and does not bind [³H]di-isopropyl fluorophosphate. Purified azurocidin kills *E. coli*, *Streptococcus faecalis* and *C. albicans in vitro*, showing optimal activity under acidic conditions (pH 5.5) in low ionic strength media. It displays considerable activity against deep rough mutants of *S. typhimurium* and, at 5 µg ml⁻¹, is also active against many other gram-negative bacteria, although *Proteus mirabilis*, *Proteus vulgaris* and *Serratia marcescens* are relatively resistant. Like defensins, azurocidin is a chemoattractant for T lymphocytes and monocytes. Autoantibodies to azurocidin (and other neutrophil granule proteins) are found in some patients with vasculitis.

Lysozyme

Lysozyme was described by Fleming, who noted both its wide distribution and its remarkable ability to lyse certain gram-positive bacteria, such as *Micrococcus lysodeikticus*. Lysozyme is a very cationic protein of approximately 14.4 kDa. Its enzymatic activity is directed against the β1-4 glycosidic bond between N-acetylglucosamine and N-acetylmuramic acid resi-

dues, which stabilizes many bacterial cell walls. Not only is lysozyme a component of PMN, monocyte and macrophage granules, it is also found in blood plasma, tears, saliva and airway secretions.

Unlike the other major granule proteins of neutrophils, lysozyme is proportionally distributed between both azurophil and specific granules. The PMNs of certain mammalian species are relatively lysozyme deficient and leukocyte lysozyme deficiency occurs sporadically in rabbits and routinely in cattle and rhesus monkey without any apparent adverse consequences. The human lysozyme gene has been localized to chromosome 12, and its organization with four exons and three introns is homologous to the lysozyme gene in chickens as well as to the human α-lactoglobulin gene.

Other gram-positive bacteria susceptible to the lytic action of lysozyme include *Bacillus subtilis* and *Bacillus megaterium*. Most gram-negative bacteria are resistant, unless also exposed to the synergistic bactericidal activity of antibody and complement or hydrogen peroxide-ascorbic acid. This resistance has been attributed to modifications of the peptidoglycan of resistant gram-positive species and to the protective effect of the outer membrane's LPS layer in gram-negative bacteria. *C. albicans* is also killed by lysozyme, especially when incubations are conducted in solutions of very low ionic strength. There is considerable evidence that lysozyme, like cathepsin G, can exert bactericidal activity by nonenzymatic mechanisms. For example, the oral bacterium *Str. sanguis* is killed by lysozyme without lysis, and inactivation of muramidase activity by sulfhydryl reduction has no effect on its bactericidal potency. The ability of lysozyme (and lactoferrin) to bind proteins modified by advanced-glycation-end(AGE)-products may contribute to the impaired resistance of diabetics to certain infections. AGE-product binding was attributed to a single AGE-binding domain in lysozyme (and two such domains in lactoferrin), each domain containing a 17-18 amino acid, cysteine-bounded, hydrophobic loop motif. Possibly such domains exist in lysozyme and other antimicrobial molecules to enhance their ability to bind to the glycosylated surfaces of host cells or microorganisms.

Lactoferrin

Lactoferrin is a 78 kDa, slightly basic, single-chain glycoprotein that can bind one or two molecules of ferric iron. It is a principal component of the neutrophil's specific granules, but is absent from azurophil granules. Free lactoferrin is found in human serum, tears, semen, milk and other secretions. The

lactoferrin gene has been localized to chromosome 3q1–23, nearby to genes that encode transferrin, a homologous protein that is the principal iron-binding glycoprotein of serum, and transferrin receptors. Three forms of lactoferrin have been described (α , β and γ), two of which also possess RNAase activity. Intestinal cells and mononuclear phagocytes have surface receptors for lactoferrin but do not synthesize it. Certain bacteria (e.g. *N. gonorrhoeae*, *N. meningitidis* and *Moraxella catarrhalis*) also possess lactoferrin receptors, and can use these to obtain iron.

Since bacteria require iron in order to synthesize essential components such as cytochromes and iron-sulfur proteins, the tight binding of Fe^{3+} by lactoferrin and its high local concentrations may leave insufficient free Fe^{3+} to support bacterial population growth. Although the bacteriostatic effects of lactoferrin can be abolished by saturating the medium with iron, bacteria subjected to iron-free apolactoferrin are often not rescued by subsequent exposure to iron-containing growth media. In addition to microbiostatic effects mediated via iron depletion, lactoferrin can also exert bactericidal effects against many microbes. Lactoferrin or lactoferricin-treated gram-negative bacteria were noted to release LPS, develop electron-dense 'membrane blisters' and become sensitized to lysozyme – all of which suggest the causation of outer membrane damage. Lactoferrin was shown to bind with high affinity to bacterial LPS, and also binds to bacterial porins and glycosylated proteins. These properties were found to reside in the N-terminal portion of the lactoferrin molecule. Exposure of lactoferrin to pepsin (its normal fate when ingested in milk) releases an antimicrobial polypeptide, 'lactoferricin', that is also derived from the N-terminal lactoferrin residues. This peptide was reported to kill many bacteria and *C. albicans*, but was ineffective against *Proteus* and *Serratia* species and *Pseudomonas cepacia*. Lactoferrin had also been noted to inhibit the adherence to and invasion of epithelial cells by certain microorganisms, and may also contribute to host defense in this manner.

Cathelin-associated peptides

The neutrophils of pigs, cattle and sheep contain an array of structurally-diverse antimicrobial peptides, all of which are synthesized at the C-terminal portion of precursors that contain a highly conserved 'cathelin' domain, approximately 100 amino acids long. Some of these cathelin-associated peptides were predicted to have amphipathic α -helical structures, while others formed compact, defensin-like β -sheet structures that were stabilized by intramolecular cystine disulfide bonds. Other cathelin-associated pep-

tides are incredibly rich in proline or tryptophan residues, and some are cyclic. In pigs, the genes for cathelin-associated antimicrobial peptides contain four exons, the first three of which encode almost the complete cathelin domain, while exon IV specifies the last few cathelin residues (including its conserved valine cleavage site), followed by codons for the mature peptide. The highly conserved 5' flanking sequences of this gene family contained NF κ B, IL-6, GM-CSF and NF-1 binding motifs, suggesting that peptide synthesis may respond to mediators generated early during infection.

A cathelin-associated peptide called either FALL-39 or hCAP-18 has also been detected in humans. It is synthesized at the carboxy-terminal portion of a 170 amino acid, cathelin-containing precursor and it is stored in the specific granules of mature human neutrophils as a 19 kDa propeptide. Substantial amounts of mRNA for this peptide were also detected in human testis. A 39 amino acid residue peptide containing the inferred mature peptide has been synthesized, and was found to exhibit antimicrobial activity and to form a perfect amphipathic α -helix throughout much of its length.

Eosinophils

Although eosinophils are usually considered as major contributors to host defenses against helminths, they resemble neutrophils in possessing chemotactic, phagocytic and microbicidal activity. Eosinophils kill bacteria and fungi by oxidative and nonoxidative mechanisms, although the composition of their molecular armamentarium differs from that of neutrophils. For example, instead of myeloperoxidase, which catalyzes the generation of hypochlorous acid and chloramines in neutrophils, eosinophils contain a structurally distinct peroxidase that produces hypobromous acid and bromamines. The principal nonoxidative microbicidal polypeptides of eosinophils include major basic protein (MBP) and eosinophil cationic protein (ECP), both of which also kill helminths and protozoa. MBP is a small, basic and arginine-rich peptide (pI 10.9, M_r 13.8 kDa) that comprises up to 50% of the total protein in guinea pig eosinophil granules. ECP is a larger molecule (M_r 18–21 kDa) that contains a high content of arginine, proline and cystine (pI > 11). Unlike MBP, which occupies the crystalloid core of the eosinophil's distinctive cytoplasmic granule, ECP is located in the granule's matrix. ECP shows sequence homology to ribonucleases and demonstrates ribonuclease activity. ECP and MBP killed *E. coli* by similar but nonidentical mechanisms, each marked by a sequential attack on the organism's outer and inner membranes. ECP

also forms relatively nonselective pores in artificial model membranes.

Mononuclear phagocytes

Although monocytes and macrophages play crucial roles in host defense against facultative and obligate intracellular parasites, their nonoxidative mechanisms for killing intracellular organisms or inhibiting their replication are not well understood. This may be due to the inherent complexity of the mononuclear phagocyte system, interspecies differences and the multiple effects of activation, differentiation and immunoregulatory cytokines on macrophage composition and function. It may also be that macrophages follow 'just-in-time' manufacturing principles for producing antimicrobial peptides and proteins, rather than stockpiling them in cytoplasmic granules in the manner of neutrophils and eosinophils. Strong evidence supporting the existence of nonoxidative antimicrobial mechanisms has been adduced from studies with diverse organisms, including *Toxoplasma gondii*, *Trypanosoma cruzi*, *Chlamydia psittaci*, *Candida albicans*, *Aspergillus fumigatus*, *Mycobacterium bovis* and *Mycobacterium tuberculosis*. Most macrophages contain lysozyme and type 2 phospholipase A₂, and some, such as rabbit alveolar macrophages, contain defensins. There is evidence for histone-like antimicrobial proteins in various macrophages, although their significance for antimicrobial function remains to be established. Under some circumstances, macrophage enzymes such as arginase and indoleamine 2,3-dioxygenase

may exert antimicrobial effects by depleting the environment of arginine and tryptophan, respectively. The possibility that macrophages recycle and use antimicrobial molecules initially synthesized by other cells, such as neutrophils, warrants consideration and is supported by some experimental evidence and the presence of receptors for neutrophil-derived molecules, such as lactoferrin and BPI, and the ability of macrophages to acquire neutrophil-derived molecules by pinocytosis.

MICROENVIRONMENT

Andras K Szakal, Gregory F Burton and John G Tew, Department of Anatomy, Division of Immunobiology, Virginia Commonwealth University, Virginia, USA

We define 'microenvironment' as an organized, local association of cells providing an interactive, dynamic structural or functional compartmentalization. Microenvironments may promote or regulate interactions among cells and/or molecules through biologically active molecules. The influence of microenvironments may be expressed at the organ, tissue, cellular or molecular levels.

Microenvironments within organisms evolved to subserve function. The relationship between microenvironment and the functional elements are complementary. In order to understand mechanisms operative in cellular functions, it is important to be

aware of the characteristics of the environment which may influence function.

The complex cellular and molecular interactions involved in the regulation of immune responses have generally been studied *in vitro*. Frequently, it is an implicit assumption that cells perform the same roles *in vivo* as they do *in vitro*. It should be appreciated that lymphoid organs and tissues are highly organized and that this functional architecture is destroyed in the process of cell isolation. To quote Fossum and Rolstad: 'The components must ultimately be explored in their natural context... as the whole being more than the sum of

its parts', and the whole alone represents the '*in vivo* veritas'.

Examples of microenvironments in the immune system

The thymus, a primary lymphoid organ, has two main microanatomical divisions: the cortex and the medulla. Each represents a distinct microenvironment. Maturing thymocytes acquire immunological competence as they migrate from the cortex to the medulla. The thymic cortex, where thymocytes (T cells) begin their functional differentiation and proliferation, occurs in a specially protected microenvironment. Cells in the cortex are protected from foreign, antigenic influence. This microenvironmental protection is provided by the 'blood-thymus barrier'.

Secondary lymphoid tissues and organs demonstrate increasing levels of complexity in organization. This results in increased compartmentalization of cells, each compartment typically containing cells of different types and assortment, and forming a distinct microenvironment. With the exception of diffuse lymphoid tissue composed of a random distribution of lymphoid cells in loose connective tissues, a common feature of the organization of secondary lymphoid tissues is the presence of lymphoid follicles (also called nodules). These structures represent the functional building blocks of the immune system responsible for the development and maintenance of humoral immunity. Lymphoid follicles are found as solitary nodules or as aggregates (e.g. Peyer's patches) associated primarily with the mucosa of respiratory and digestive tracts. In the lymph node, lymphoid follicles are located in the cortex and, in the spleen, in the splenic white pulp.

The microenvironment surrounding lymphoid nodules may vary according to their location. For example, in Peyer's patches, one of the mucosal-associated lymphoid tissues (MALT), lymphoid follicles are intimately associated with the mucosal epithelium of the ileum. In lymph nodes, a close association exists between the lymphoid follicle and the subcapsular (or marginal) sinus (a lymphatic channel) of the lymph node. In the spleen, lymphoid follicles are surrounded by the marginal sinuses (blood sinuses). In all cases these microenvironmental associations control the access of antigens to the B cells of lymphoid follicles, but in each case by somewhat different cellular mechanisms.

In the epithelium overlying Peyer's patch follicles, specialized M cells transport antigen through an intracellular route from the intestinal lumen to B lymphocytes of the follicles for sensitization. Other

epithelial cells exert influence at the molecular level on the immunoglobulin A (IgA) produced by sensitized B cells of the MALT. For example, during the intracellular transport of the IgA antibody to mucosal surfaces by epithelial cells, an IgA-associated glycoprotein molecule termed 'secretory component' is produced by proteolytic cleavage of the epithelial cell poly-Ig receptor. Secretory component protects the IgA from break down by the lysosomal system of the epithelial cell during intracellular transport and also from the enzymes found on mucosal surfaces. The evolution of this remarkable cooperation of IgA-producing cells with epithelial cells is a good example of microenvironmental influence at the molecular level.

A lymphoid follicle is a compartment of primarily B cells which represents a unique microenvironment. Upon antigenic stimulation, lymphoid follicles develop germinal centers, which constitute the primary sites of B memory cell production. This response to antigenic stimulation is referred to as the 'germinal center reaction' and is dependent on the transport of antigen to the lymphoid follicle and on the interaction between T and B cells, which in turn depends on the unique intrinsic organization of the lymphoid follicle microenvironment. This is a dynamic environment and its organization is intimately related to one of its cellular components, the follicular dendritic cell (FDC). FDCs are nonphagocytic cells capable of trapping and retaining antigen on the surface of their dendrites in the form of immune complexes which function in the maintenance phase of humoral immunity. The functional role of the lymphoid follicle microenvironment in the development of the germinal center reaction is best illustrated by the successive cellular events leading to the production of B memory cells. As an example, we will focus on the cellular events as they occur in the lymph node (Figure 1).

The lymph node lymphoid follicles are closely associated with the subcapsular sinus (Figure 1). At its deep or paracortical poles, lymphoid follicles are in the proximity of high endothelial (postcapillary) venules draining blood from the net of capillaries surrounding each follicle. In immune animals, antigen arriving at the lymph node via afferent lymphatics enters the subcapsular sinus in the form of immune complexes. From there, antigen is transported by a cell-mediated process to the lymphoid follicle (see Figure 1). Recirculating antigen-specific clones, on arriving at the high endothelial venules in the blood, recognize this specialized endothelium and migrate through the wall of the venule to the lymphoid follicle. These recirculating lymphocytes normally leave the follicle via the lymph node medullary

Figure 1 Development of microenvironment during the germinal center reaction. Based on current concepts, the left side illustrates the trapping of soluble immune complexes by FDCs, and the cellular events leading to the production of B memory cells in the germinal center. The right side illustrates the trapping of a replicating antigen such as the retrovirus, HIV, and the role FDCs play in the infection of CD4⁺ T cells. For interpretation of events, see text. cords and sinuses to return to the blood. However, the antigen-specific lymphocytes are retained in the follicle by a special cellular 'spongework', formed by FDCs. This spongework develops as a sequel to the transport of antigen from the subcapsular sinus (see Figure 1). The antigen is transported on the surface of nonphagocytic antigen-transporting cells of varying dendritic morphology. These cells are thought to be precursors of FDCs. On arrival at the lymphoid follicle, the spongework, a three-dimensional network or reticulum, is established by the FDCs intertwining their dendritic processes (see Figure 1).

This spongework is generally referred to as the 'antigen-retaining reticulum' since its component FDCs are capable of retaining antigen on their surfaces in an intact form for months to years. It is located in the region of the lymphoid nodule closest to the subcapsular sinus. The spaces within the spongework are filled mostly by B lymphocytes from the recirculating pool. Some T helper cells are also found here. According to consensus, antigen-specific B cells are removed from the recirculating pool of lymphocytes by binding to the antigen on the surface of FDCs. Thus, this spongework of FDCs forms a specialized microenvironment that brings together antigen, specific B cells, and T helper cells and provides an optimal framework for their interaction.

The antigen-retaining reticulum is a dynamic structure. It develops rapidly during the first 3 days after the introduction of antigen into the region of the animal drained by the lymph node. Electron microscope studies show that during this time the initially smooth, elongated filament-like dendritic processes of these 'octopus-like' FDCs mature to become 'beaded'. These beads or bodies, through an interaction with other FDCs, concentrate immune complexes on their surfaces to become immune complex-coated bodies or iccosomes, which are then released and dispersed in the microenvironment (see Figure 1). This process is accompanied by edema, resulting in an increase in the intercellular spaces, apparently to facilitate iccosome dispersion and cell traffic. The free iccosomes, shown to be many times more immunogenic than free immune complexes, are endocytosed by the recruited B cells. The endocytosed antigen is fragmented in lysosome-like vesicles of the B cells. These antigen fragments then become associated with the Golgi apparatus which is known to be functional in antigen re-expression on the cell surface. Functional studies show that these B cells can present the antigen efficiently to T helper cells (see Figure 1), which are also present in the microenvironment of the antigen-retaining reticulum. This process lasts for about a week. As a sequel to antigen presentation, T cell lymphokines

(interleukins) active within the microenvironment induce proliferation and maturation of B cells. This represents the initiation of germinal center development, leading to B cell memory.

Germinal center development is represented by the proliferative response of specific B cells in the lymphoid follicle which increases through day 10 after antigen exposure and then gradually declines. This proliferative expansion of B cells establishes another compartment and microenvironment. The germinal center developed is situated toward the medullary pole of the lymphoid nodule beneath the antigen-retaining reticulum of FDCs. Soon after the initiation of germinal center development, macrophages typically found in germinal centers migrate into this region. These cells are termed tingible body macrophages (TBM) on account of the stainable (tingible) remnants of phagocytosed germinal center B cells (see Figure 1). Thus, the microenvironment of germinal centers is represented by the proliferating (IgD⁺, IgM⁺) B cells and TBMs. The significance of TBMs in germinal centers was recently related to affinity maturation of B cells. The germinal center microenvironment has the features required for affinity maturation. These include: 1) availability of antigen on nearby FDCs for selection of high affinity B cells; 2) rapid proliferation of B cells allowing for expression of V gene mutations; 3) elimination of B cells in large numbers by TBMs (i.e. B cells not rescued by binding of antigen due to lack of specificity or mutation to decreased affinity for the antigen) (see Figure 1). Thus, affinity maturation could be explained in terms of the germinal center microenvironment.

We have stated that microenvironments evolved to subserve function. This function ultimately may be the elimination of specific microorganisms. Some microbes, however, have evolved through the age-old association with the defensive mechanisms of a microenvironment to subvert its protective features to their own ends. This appears to be the case with retroviruses. The trapping of retroviruses by FDCs, as antigens, was first demonstrated by Szakal and Hanna in 1967. A follow-up study, using Rauscher leukemia virus, showed that B cells were at risk of infection when coming in contact with the FDC-retained virus. That this follicular microenvironment plays a very important role in the acquired immune deficiency syndrome (AIDS) pathogenesis induced by the retrovirus, human immunodeficiency virus (HIV), was only recently realized.

Shortly after primary infection, HIV viremia occurs and the immune system responds with virus-specific cells and antibodies. Virus is complexed with antibody and trapped on the extracellular surfaces

of FDCs in much the same manner as conventional antigens (see right side of **Figure 1**). Throughout most of the disease process, HIV remains on the FDC reticulum. However, eventually the FDCs are destroyed, the lymphoid tissues involute and systemic HIV replication and marked immunosuppression ensue. In 1993, Fauci and colleagues and Haase and coworkers showed that throughout the clinically latent phase of the disease (typically lasting several years), active HIV infection is ongoing in, and virtually confined to, lymphoid follicles. It was postulated that virus on FDC might infect CD4-bearing T cells migrating into germinal centers to participate in T cell-dependent humoral responses. However, it remained to be shown that FDC-trapped HIV was infectious, since it was complexed with antibodies, including some with neutralizing activity. Recently, our group showed that HIV immune complexes on FDC are highly infectious. Even more remarkably, when HIV is complexed with very high levels of neutralizing antibodies, infection persists when FDCs are present. In contrast, the same concentrations of neutralizing antibody and virus do not cause infection in the absence of FDCs, thus supporting the importance of the follicular microenvironment. Other features of this specialized microenvironment that may also contribute to HIV pathogenesis might include:

1. the high degree of cellular activation and potent costimulatory signals present there;
2. the ability of FDCs to retain antigens and viruses for long periods in an unprocessed or 'active' form; and
3. protection from antiretroviral agents which are designed to attack replicating intracellular virus but not the extracellular (nonreplicating) FDC-associated HIV. A better appreciation of specialized microenvironments may help us in future years to devise improved intervention strategies for retrovirus-induced disease.

Microenvironments are ubiquitous in the body. They are not limited to the above examples selected to illustrate the importance of the concept of microenvironment under normal physiological and in pathological conditions. Some microenvironments are well-characterized, others are yet to be defined. The knowledge of the function of any system is inseparably bound to its microenvironment.

MINOR TRANSPLANTATION (HISTOCOMPATIBILITY) ANTIGENS

Elizabeth Simpson, MRC Clinical Sciences Centre, RPMS, London, UK

Snell discovered the existence of minor transplantation antigens at the same time that he discovered H2, the major histocompatibility complex (MHC) of the mouse. This discovery came from experiments using the classic genetic approach of crossing,

backcrossing and intercrossing two genetically dissimilar inbred mouse strains and examining the ability of tissues from the progeny of these crosses to stimulate a graft rejection response in one of the parental strains. Another, complementary, test was

to examine the ability of the progeny to reject a tumor of parental strain origin. The results of these tests indicated the pattern of inheritance and co-dominant expression of transplantation antigens from one strain when placed by breeding on the background of the other strain.

Snell found that the strongest (hence major) transplantation antigen segregated in a Mendelian fashion as a single locus, which he named H2 because it was numerically the second one he described from these experiments. His collaborative work with Gorer established that the antibodies Gorer had made by immunization with tissues between different mouse strains were directed against Snell's H2 antigens.

However, the genetic experiments which led to the discovery and subsequent characterization of the major transplantation (or histocompatibility, as termed by Snell) antigens, H2 in mouse, also showed that there were a large number of other transplantation (histocompatibility, H) antigens independently segregating in the backcross mice. These were given numbers (H1, H3, etc.) in the order in which they were discovered. Snell and Bailey isolated each by continued backcrossing, to generate the minor H congenic strains, each of which consisted of the selected trait, the minor H antigen (as measured by grafting or tumor rejection) of one, donor strain, expressed on the genetic background of the other, recipient parental strain. A congenic strain is therefore identical with the recipient parental strain except for the chromosomal segment incorporating the donor gene whose product has been selected for.

In reality, that chromosomal segment is of variable length and contains other 'passenger' genes. Where these are polymorphic between donor and recipient parental strains, their presence allowed the chromosomal mapping of a number of minor transplantation antigen genes. It is these and other similarly derived minor H congenic strains which have established the *in vivo* definition of minor H (transplantation) antigens, and there are now several dozen of them.

The strength of each antigen can be measured by the length of time it takes to reject skin grafts exchanged between the congenic and the parental strains. The alleles of some (e.g. H1, H3, H4, H7 and H25) are quite strong and give rejection times of between 2 and 4 weeks (in comparison with H2 mismatched grafts, where the rejection time is 1–2 weeks). Generally, there appear to be a limited number of alleles of each minor H antigen and this also distinguishes them from the highly polymorphic H2 antigens. The alleles of a particular minor H antigen in different inbred strains can be determined by grafting *in vivo* in genetic complementation experi-

ments or *in vitro* using minor H-specific, MHC-restricted cytotoxic T cells (see below).

MHC-restricted responses to minor H antigens *in vivo* and *in vitro*

In the mid-1970s, several months after MHC-restricted responses to viruses by cytotoxic T cells were first reported by Zinkernagel and Doherty, two laboratories reported similar MHC-restricted cytotoxic T cell responses specific for minor H antigens. One was that of Bevan, who in secondary mixed lymphocyte culture (MLC), raised MHC-restricted responses to the multiple H antigens by which two MHC-matched inbred strains differed. The other was that of Simpson, who likewise found cytotoxic T cell responses in secondary MLC to the male-specific transplantation antigen, H-Y, to be MHC-restricted.

Subsequently, MHC-restricted minor H-specific cytotoxic T cell responses have been obtained by immunizations between minor H congenic and their recipient parental strains. Alleles of loci stimulating rapid *in vivo* responses generally give good cytotoxic T cell responses following secondary MLC *in vitro* but the strongest *in vitro* responses are obtained from MHC-matched strains differing at multiple minor H loci, presumably due to the activation of a large number of different clones of different specificities. Both Tomonari and Roopenian have isolated T cell clones specific for various minor H antigens present on the immunizing cell from murine secondary MLC and these include not only class I-restricted CD8 but also class II-restricted CD4 clones.

The work of Matzinger has shown that *in vivo* responses to minor H antigens are also MHC-restricted. There is good evidence that both *in vivo* and *in vitro* it is necessary to have concomitant activation of both CD8⁺ and CD4⁺ T cell subpopulations in order to generate either a graft rejection or a cytotoxic T cell response against minor H antigens.

As a corollary, at least two epitopes, restricted respectively by MHC class I and II molecules, and probably encoded by different genes, are necessary to stimulate *in vivo* graft rejection. This has been demonstrated in mice by genetic and molecular genetic approaches.

In humans, the genetic analysis of T cell responses to minor H antigens is much more difficult, because here we are dealing with an outbred population in which the MHC restriction elements (HLA encoded) necessary for the recognition of the minor H antigen are independently segregating, and it is likely that individuals will be heterozygous for alleles of transplantation antigens. Human families are also small and one cannot do the genetic experiments possible

in mice. However, it is quite clear from clinical interventions involving exchange of organs or tissues between MHC-matched but genetically non-identical humans that graft rejection responses include components directed against transplantation antigens encoded outside the MHC. Thus, it is still necessary to use immunosuppression for kidney grafts from HLA-matched donors and for bone marrow transplants from HLA-matched siblings which can give rise to intractable graft-versus-host disease directed against non-MHC transplantation antigens. It is from such patients that Goulmy has isolated *in vitro* HLA-restricted T cell clones with specificities that look remarkably similar to those of the minor H antigens in mouse. One such specificity is the male-specific minor H antigen, H-Y, others are five specificities named HA-1 to HA-5 whose segregation in families and in unrelated individuals expressing the appropriate HLA restriction molecules has been studied.

Molecular identification of minor H antigens

Minor H antigens in mice and humans appear to be recognized *in vivo* and *in vitro* by T cells but not antibodies. This has made it difficult to explore their molecular nature. However, over the past 6 years, initially from the work of Rammensee and colleagues, it became clear that the various epitopes of minor H antigens were peptides derived from endogenous proteins, loaded during the biosynthesis of MHC molecules into their peptide-binding grooves and then expressed at the cell surface. It is thus polymorphic differences of the proteins from which the MHC-binding peptides are derived which are recognized by T cells, in much the same way as they recognize peptides derived from viral proteins in a virus-infected cell. More recently, certain minor H peptides and their encoding genes have been identified by the use of two complementary approaches:

1. the elution of peptides from MHC molecules and
2. expression cloning using T cell clones to detect the products of transfected genes.

The peptide elution approach identified the first human minor H component, HA2, and one of the H-Y peptide epitopes in humans, whilst the expression cloning approach has identified several different H-Y peptide epitopes in mice as well as an increasing number of tumor-specific transplantation antigens in humans and mice, from the pioneering work of Boon's laboratory.

Selection of the T cell repertoire: involvement of minor H antigens

The generation of the T cell repertoire during differentiation in the thymus involves selection. T Cells which express rearranged T cell receptor (TCR) genes encoding high-affinity self-MHC plus peptide-reactive receptor molecules are removed by apoptosis (negative selection). Those which express TCR with a lower affinity for self-MHC molecules are positively selected and exported to the periphery. There they can become activated and clonally expanded by encounter with antigen-presenting cells having novel peptides, for example derived from viruses or bacteria, bound by their MHC molecules, if the novel peptide-MHC complex creates a higher affinity interaction with the TCR. Those TCR expressed in the thymus that have too low an affinity for self-MHC molecules are not selected and die 'from neglect'. It is therefore clear that MHC-binding self-peptides expressed in the thymus can play an important role in shaping the T cell repertoire and can thereby contribute to the capacity to mount effective immune responses to pathogens and certain tumors, and to the propensity to mount autoimmune responses.

Aspects of this are well-illustrated by the first T cell receptor transgenic mouse described, with a virtually monoclonal T cell population expressing a receptor specific for an H-Y epitope presented by H2D^b molecules. Female transgenic mice expressing H2D^b molecules show characteristic thymic development with generation of single positive CD8⁺ T cells from their double positive, CD4⁺8⁺ precursors and export to the periphery of CD8⁺ cells, whereas in females of H2 haplotypes lacking H2D^b, positive selection is faulty, and few thymocytes progress past the immature double positive, CD4⁺8⁺ stage. Male transgenic mice expressing the H2D^b molecule show dramatic negative selection, with apoptosis removing most of the CD4⁺8⁺ immature thymocytes, and reducing the thymus to less than 10% of the size and cellularity of that in females.

An example of non-MHC genes which may encode polymorphic proteins affecting the propensity to develop autoimmunity has been found from studies of the NOD (non-obese diabetic) strain of mice. A number of chromosomal localizations of genes predisposing to susceptibility or resistance to diabetes have been identified from the extensive backcross studies of Todd and Wicker. It is possible that some of these may act by affecting T cell repertoire selection, for example by negative selection, similar to that caused by the expression of a cross-reactive self-antigen of BALB/c (H2^d) origin causing clonal deletion and thus nonresponsiveness to the

copolymer GT, to which DBA/2 (also H2^d) are responders, but BALB/c and the F1 hybrid are not.

Pathological and physiological roles of minor H antigens

Minor transplantation antigens were discovered experimentally by skin and tumor grafting and are manifest clinically as impediments to the exchange of therapeutic grafts of MHC-matched tissues or organs between genetically dissimilar individuals. Graft-versus-host disease following bone marrow transplantation can cause severe pathology, and host-versus-graft can lead to the rejection of donor organs of tissues. It is possible that in the future the identification of immunodominant minor transplantation antigens may lead to better avoidance or treatment of these consequences of transplantation. A physiological role of minor transplantation antigens, i.e. self-peptides bound by self-MHC molecules, may be reflected by T cell repertoire selection. This however may be merely a consequence of evolutionary selection for variants of many genes involved in diverse functions, but whose protein products are sampled as MHC-binding peptides. The T cell immune system is highly evolved to detect these, as they do not differ qualitatively from peptides of viral or bacterial origin.

MIXED LYMPHOCYTE REACTION

Jonathan Sprent, Department of Immunology, The Scripps Research Institute, La Jolla, California, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Historical background

Until the early 1960s small lymphocytes were regarded as short-lived resting cells of obscure function. In 1962 Gowans and his colleagues observed that purified small lymphocytes transferred from thoracic duct lymph of rats were able to transform into blast cells when injected into irradiated mice. This experiment provided the first unequivocal evidence that small lymphocytes were capable of being triggered to enter cell cycle. Two years later, independent studies by Bain and colleagues and by Bach and Hirschorn demonstrated that a mixture of blood leukocytes taken from two unrelated donors generated large numbers of blast lymphoid cells after several days in tissue culture. Bain and colleagues made the critical discovery that blast transformation failed to occur between cells from monozygotic twins. Shortly afterwards other workers demonstrated that the mixed leukocyte reaction (MLR) was demonstrable in a number of different species and that the strongest reactions occurred with disparity at the major histocompatibility complex (MHC), i.e. the HLA complex in man and the H-2 complex in mice. With the discovery that small lymphocytes were divisible into thymus-derived (T) and bone marrow-derived (B) cells, the MLR was shown to reflect the proliferative response of T cells, with few or no B cells involved as responding cells.

Technical features

When untreated lymphoid cells from two different individuals are cultured together, the resulting MLR is bidirectional. Thus, with a mixture of homozygous MHC-incompatible *a* and *b* lymphoid cells, the response involves *a* T cells reacting to *b* alloantigens plus *b* T cells responding to *a* antigens. In accordance with the classic laws of transplantation immunity, only *a* T cells proliferate when homozygous *a* lymphoid cells are cultured with heterozygous (*a* × *b*)F₁ cells. Bidirectional responses occur with a mixture of (*a* × *b*)F₁ and (*a* × *c*)F₁ cells.

To ensure that the MLR is unidirectional, one of the two populations of lymphoid cells is generally treated with mitomycin C (an inhibitor of DNA synthesis) or subjected to irradiation. Such treatment of the stimulator population destroys or inactivates T cells in this population but does not interfere with

the immunogenicity of the treated cells. As discussed below, the stimulatory function of lymphoid cells is restricted to specialized antigen-presenting cells (APCs). These cells are highly radioresistant and do not divide in culture.

As with any assay system conducted *in vitro*, the magnitude of the MLR depends critically upon the quality of the tissue culture conditions used. To obtain high responses it is essential to use fully viable cells and a tissue culture medium containing all essential nutrients; addition of serum (1–10%) and 2-mercaptoethanol is usually found to be critical. As responder cells, any population containing a high proportion of T cells can be used. Buffy coat white blood cells are employed as responders (and stimulators) for MLR in humans. For rodents, lymph node (LN) cells give near-optimal data, although most investigators tend to use spleen cells. MLRs with spleen cells, although adequate, are lower than with LN cells (because of the lower content of T cells in spleen) and are often associated with high background responses, i.e. responses with syngeneic stimulators. The best results are obtained with purified T cells as responder cells.

Typical MLRs are usually conducted in 96-well plates in 200 µl volumes, using 5×10^4 to 2×10^5 responder cells and 5×10^5 allogeneic versus syngeneic stimulator cells. Proliferative responses are quantitated by adding [³H]thymidine (³HTdR) (1 µCi per well) to the cultures after 1–6 days and harvesting the cultured cells 6–24 hours later to measure ³HTdR incorporation. With low doses of responder cells, e.g. 5×10^4 , responses generally reach peak levels on day 6 or later. With higher doses of responders, peak responses occur earlier.

For rodents, the magnitude of the MLR depends critically upon the health of the animal colony. Rodents with chronic viral infections generally give rather low MLR, probably because of toxic cytokines or other mediators released by infected macrophages. In this situation, addition of the prostaglandin inhibitor, indomethacin, to the culture often improves the results.

Target antigens

Primary MLRs are directed almost exclusively to gene products of the MHC. The MHC encodes two broad classes of cell surface molecules, termed class

I and class II. Class I molecules are expressed on virtually all cell types. Class II molecules, by contrast, show a much more limited distribution with high expression restricted to B cells, macrophages and dendritic cells; in humans, class II molecules are expressed on T cells, but only after activation. Both classes of MHC molecules show extensive polymorphism. According to the literature, class II alloantigens provide a much stronger stimulus for primary MLRs than class I alloantigens. As discussed later, however, it has recently become apparent that class I alloantigens can elicit strong MLRs under certain conditions.

The mouse provides the one exception to the rule that MLRs are directed almost exclusively to MHC alloantigens. In this species, very powerful MLRs can be stimulated by Mls determinants. These antigens display limited polymorphism and represent endogenous superantigens encoded by mouse mammary tumor virus (mtv) genes. Only a small proportion of mtv antigens elicit strong primary MLRs; these particular mtv antigens are termed Mls antigens. Since mtv antigens bind to T cell receptor V_{β} epitopes, MLR to mtv antigens are V_{β} specific. It should be noted that H-2 and Mls molecules are unrelated and are encoded on different chromosomes. To date, Mls molecules have not been described in other species.

For MHC alloantigens, there is increasing evidence that MLRs are not directed to MHC epitopes *per se* but to a broad array of self peptides bound to MHC molecules. Most of these peptides are presumably derived through breakdown of various intracellular proteins involved in cell metabolism.

Precursor frequency of participating T cells

The precursor frequency of unprimed T cells responding to typical non-MHC antigens, e.g. viral or foreign protein antigens, is extremely low (≤ 1 in 10^5). Responses to MHC alloantigens, by contrast, involve a very high proportion of T cells. Working with rat lymphocytes in the late 1960s, Wilson, Blyth and Nowell estimated that 2–3% of unprimed T cells responded to stimulator cells from an MHC-different rat strain. Subsequent studies of others with mice gave similar data.

In view of the extensive polymorphism of MHC molecules, it is probable that the vast majority of T cells have the potential to display alloreactivity for at least one of the many different MHC alloantigens expressed in the species as a whole. In support of this idea, many T cell clones with defined self MHC-restricted specificity (specificity for antigen com-

plexed to self MHC molecules) have been shown to display dual reactivity for particular MHC alloantigens. Since T cells recognize conventional (non-MHC) antigens and MHC alloantigens via the same antigen-specific $\alpha\beta$ T cell receptor (TCR), these two classes of antigens are presumed to express cross-reactive epitopes. Why T cells have such a high precursor frequency for MHC alloantigens, however, is still something of a mystery.

Ontogeny

As with responses to other antigens, the response of T cells to MHC alloantigens is limited to mature lymphocytes. Most thymocytes are immature, and MLRs with unseparated thymocytes are 20–50-fold lower than with extrathymic T cells. The limited response observed with thymocytes is restricted to the minor (5–10%) subset of mature thymocytes. Mature T cells are not evident in the thymus until relatively late in development (just before birth in mice) and early thymocytes are incapable of giving an MLR. Some immature thymocytes do have specificity for MHC alloantigens (and self antigens) but these cells are highly susceptible to tolerance induction when exposed to these antigens. As first shown for skin graft rejection by Medawar and colleagues, exposure of early T cells to MHC alloantigens results in a state of specific immunological tolerance: T cells specific for the MHC alloantigens are deleted in the thymus, with the result that the T cells exiting from the thymus are unable to produce an MLR to these antigens. A similar mechanism causes T cells to show unresponsiveness to self MHC molecules.

Response of $CD4^+$ versus $CD8^+$ cells

The expression of $CD4^+$ and $CD8^+$ cell surface 'accessory' molecules divides mature T cells into two functionally distinct subsets. Whereas most thymocytes express both CD4 and CD8 molecules, the expression of these molecules on mature extrathymic T cells is mutually exclusive. CD4 and CD8 molecules augment T cell signaling by focusing src family kinases such as $p56^{lck}$ in the vicinity of the TCR. In addition, CD4 and CD8 molecules bind to nonpolymorphic sites on MHC molecules. Such binding is believed to strengthen the interaction of the TCR with the polymorphic (antigenic) sites on MHC molecules. The binding specificity of CD4 and CD8 molecules is MHC class specific. Thus CD4 molecules bind selectively to class II molecules, whereas CD8 molecules bind to class I molecules. As discussed below, the MHC class specificity of CD4 and CD8 molecules strongly influences the allospecificity of T cells bearing these molecules.

When monoclonal antibodies (mAbs) specific for CD4 versus CD8 molecules became available about 15 years ago, it became possible to prepare highly purified populations of CD4⁺ and CD8⁺ cells. Testing the MHC class specificity of these T cell subsets is most easily addressed by using stimulator cells expressing only one class of alloantigen, e.g. class II alloantigens but not class I antigens. The mouse is ideal for such studies as a wide variety of H-2 recombinant and H-2 mutant strains are available. For example, to examine responses directed selectively to H-2 class II alloantigens one can employ the combination of C57BL/6 (B6) (H-2^b) and bm12; these two strains are identical except for three amino acid differences in the I-A^b (class II) molecule. Similarly, the combination of B6 and the class I (K^b) mutant bm1 can be used to study responses directed selectively to class I alloantigens. When B6 T cells are separated into subsets and tested for MLR against bm12 versus bm1 stimulator cells (Figure 1), B6 CD4⁺ cells give high MLR to class II-different bm12 stimulators but almost no response to class I-different bm1 stimulators. Conversely, B6 CD8⁺ cells respond very strongly to bm1 stimulators but give negligible responses to bm12. These data indicate that the alloreactivity of CD4⁺ and CD8⁺ cells shows stringent MHC class specificity, with CD4⁺

cells controlling anti-class II responses and CD8⁺ cells accounting for anti-class I responses.

The evidence that purified CD8⁺ cells can produce a primary MLR deserves comment as the literature is entrenched with the dogma that the response of CD8⁺ cells depends critically upon the presence of cytokines derived from CD4⁺ cells. This view is clearly untenable in the B6 anti-bm1 response because the MLR of B6 CD8⁺ cells responding to bm1 stimulators is not affected by adding CD4-specific mAb to the cultures or by depleting the stimulators of T cells (a possible source of cytokines). It should be stressed, however, that the capacity of murine CD8⁺ cells to produce primary MLRs in the absence of added cytokines shows considerable strain variation. Thus, whereas some strains (e.g. B6) produce very high responses, other strains (e.g. DBA/2) give substantially lower responses. Similar findings apply with rats. The reason for this strain variation is unclear. In humans, MLR by purified CD8⁺ cells tend to be quite low unless purified dendritic cells are used as APCs. It is worth noting that MLRs by CD8⁺ cells characteristically show abbreviated kinetics and can be missed unless early time points are examined. Responses generally reach a peak on day 3–4 of culture and fall to background levels by day 6. The abrupt decline in the MLR by CD8⁺ cells may reflect the responder cells rapidly differentiating into cytotoxic cells which then destroy the APC, thereby removing the stimulus for the MLR. Alternatively, the decline in the MLR may be a manifestation of rapid consumption of interleukin 2 (IL-2) by the responder cells.

Figure 1 Time response of primary MLR by small doses (1×10^5) of B6 CD4⁺ cells (A) or B6 CD8⁺ cells (B) responding to T cell-depleted (Thy-1⁻) irradiated (1500 rad) spleen stimulators (5×10^5) from class I-different (B6 × bm1)F₁ (○), class II-different (B6 × bm12)F₁ (●) or syngeneic B6 (□) mice. T cell subsets were prepared by a combination of MaB plus complement treatment followed by positive panning at 4°C; under the conditions used the T cell subsets do not pick up antibody during the panning procedure, i.e. CD8⁺ cells are not coated with anti-CD8 mAb. The data show the mean responses of triplicate cultures; ³HdR (1 mCi ml⁻¹) was added 18 hours before harvest. It is evident that B6 CD8⁺ cells respond only to bm1 stimulators whereas CD4⁺ cells respond only to bm12 stimulators; note that the MLR by CD8⁺ cells peaks early and falls to background levels by day 6. (Data from Sprent and Schaefer (1989).)

The syngeneic (autologous) MLR

By definition, MLRs to MHC alloantigens are calculated with respect to the background response, i.e. the proliferative response to autologous or syngeneic stimulators. With unseparated T cells as responders, the proliferative response to self stimulators is usually quite low, although responses can reach appreciable levels late in culture. With purified T cell subsets as responders, the syngeneic (auto) MLR is far higher with CD4⁺ cells than CD8⁺ cells. Indeed, in the later stages of the response, the auto-MLR by CD4⁺ cells can approach the allo-MLR. The critical question of why CD4⁺ cells give a high auto-MLR in culture has yet to be resolved. In particular, it is still uncertain whether the auto-MLR reflects incomplete induction of self tolerance or simply a tissue culture artifact (e.g. a response to antigens or mitogens in the serum supplement).

Nature of APCs for MLRs

For sensitized T cells responding to MHC alloantigens, a number of different cell types such as macrophages (Mφs), dendritic cells (DCs) and B cells express APC function. Which of these cell types have APC function for unprimed T cells is controversial. One school of thought holds that unprimed T cells can be stimulated by only one type of cell, namely DCs. Others argue that, although DCs do express extremely potent APC function for unprimed T cells, significant APC function can also be provided by Mφs and B cells. For CD8⁺ cells, some workers (this writer) maintain that many different cell types, including various class II-negative cells, can express potent APC function for MHC alloantigens. Others refute this view and attest that only DCs can stimulate CD8⁺ cells.

The resolution to the issue of which particular cell types express APC function for unprimed T cells is likely to hinge on defining the precise signals required for T cell activation. In this respect, it is now well established that primary T proliferative responses require costimulatory signals delivered through T cell contact with molecules such as B7 (B7-1, B7-2) and ICAM-1 on APCs; these molecules are expressed at a particularly high level on DCs. Costimulation boosts signaling via the TCR and is crucial for the production of growth factors such as IL-2. Although costimulation is probably important for all primary responses, recent work suggests that the requirement for costimulation is less stringent for high-affinity T cells than for low-affinity cells. This could explain the different findings on the role of DCs in MLRs. Thus, with their high expression of costimulatory molecules, DCs could be crucial for stimulating T cells with low-to-average affinity for

antigen, whereas other cell types could be sufficient for stimulating high-affinity T cells.

Biological significance

The MLR is merely one of many techniques that can be used to quantitate the response of T cells to alloantigens. The limitation of the MLR is that it measures only one step of T cell induction, i.e. proliferation. To study the *differentiation* of T cells responding to alloantigens one has to use other techniques, e.g. the generation of cytotoxic lymphocytes, lymphokine production, etc. Nevertheless, the MLR is a relatively easy and inexpensive assay and this technique has produced a great deal of invaluable basic information on various aspects of the immune response, including the nature of the antigens recognized, the specificity of CD4⁺ and CD8⁺ cells and the features of APCs. The usefulness of the MLR is likely to continue for many years.

MOLECULAR MIMICRY

Alan Ebringer, Infection and Immunity Group, Division of Life Sciences, King's College, London, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The term 'molecular mimicry' was introduced in 1964, by Damian, to describe antigen sharing between parasite and host, as a way for the parasite to avoid destruction by the immune processes of the host. In the 1980s and 1990s, the term has acquired a more specific significance, in that it refers to antigens shared between an immunocompetent host and an external agent, and this leads in some cases to

pathological consequences whereby antibodies produced against the external agent will bind to the self antigens of the host and cause inflammatory damage. Rheumatic fever, ankylosing spondylitis and rheumatoid arthritis are three diseases that could be considered to provide good examples of this type of molecular mimicry.

Rheumatic fever

It has been known since the 1920s that there is a genetic element in the incidence of rheumatic fever, in that the disease is more prevalent in individuals having blood groups A and B than in those with blood group O, and Glynn has pointed out that this observation has been made in many different countries.

Rheumatic fever is a disease where the etiological mechanism has been worked out. *Streptococcus pyogenes* microorganisms infect the upper respiratory tract and, 2–3 weeks later, a generalized serum sickness-like disease develops, with fever, arthritis, sometimes chorea and carditis. Kaplan and Meyeserian demonstrated in 1962 that the damage is caused by crossreactive antibodies, which attack the cardiac valves, because self antigens in cardiac tissues resemble the antigens found in *S. pyogenes*. So here is an example of an autoimmune disease that has been triggered by an infection, because there is molecular mimicry between the human host and the bacterial infectious agent.

All blood groups have a common precursor, the H gene, which gives rise to the H substance. Individuals with blood group O express in their red cell membrane the H substance, which has a terminal carbohydrate residue (L)-fucose. Watkins, in 1966, showed that individuals with blood group A have another gene, whose gene product is a glycosyl-transferase, which adds N-acetyl-(D)-galactosamine to the preterminal galactose of the H substance. Thus individuals with blood group A have two terminal residues, N-acetyl-(D)-galactosamine and (L)-fucose. Blood group B individuals have a gene which adds (D)-galactose to the preterminal galactose of H substance, giving rise to two terminal residues, (D)-galactose and (L)-fucose. In examining the Haworth formulae of these sugars, the substitutions at every carbon atom are different between (L)-fucose and N-acetyl-(D)-galactosamine, except for the connecting first carbon atom. Heymann and colleagues showed in 1964 that the terminal sugar residue in streptococci is N-acetyl-(D)-glucosamine, which is attached to the backbone of a rhamnose polymer. The only difference between N-acetyl-(D)-glucosamine and N-acetyl-(D)-galactosamine is the hydroxyl group, which is in a different orientation on the C-4 atom of galactose. Thus, other things being equal, blood group A resembles the streptococcal antigen more than blood group O. Similarly with blood group B, where (D)-galactose is structurally closer to N-acetyl-(D)-glucosamine of *S. pyogenes* than (L)-fucose of blood group O. Therefore any antibodies produced in blood group A individuals, following infection

with *S. pyogenes*, will bind to tissue antigens containing blood group A substance and cause reactive inflammation.

Goldstein and coworkers showed in 1969 that cardiac tissue contains molecular groups similar to blood group A substance. Thus antistreptococcal antibodies should bind to such crossreacting antigens, explaining the higher frequency of rheumatic fever in individuals possessing such blood groups. It would appear that molecular mimicry provides an explanation for the higher frequency of rheumatic fever in individuals with blood groups A and B compared with individuals with blood group O. Zabris-kie and colleagues have extended this concept and showed that the chorea of rheumatic fever can also be explained by a molecular mimicry model between streptococcal antigens and basal ganglia.

Ankylosing spondylitis

Ankylosing spondylitis (AS) is a chronic inflammatory arthritis, characterized by exacerbations and remissions, affecting primarily the axial skeleton and the sacroiliac joints. In 1973 it was demonstrated by two independent groups that the class I major histocompatibility complex (MHC) molecule HLA-B27 was present in over 90% of patients with AS, while its frequency in the general Caucasian population was of the order of 8%. Clearly the HLA-B27 molecule was somehow involved in the development of the disease, but there are many healthy individuals who possess HLA-B27 but do not develop the disease.

Studies using identical twins showed that when one of the twins had AS, the chance or concordance rate of the other twin developing AS was well below 50%. A low concordance rate in identical twin studies clearly suggests the interaction of an environmental factor acting in conjunction with a genetic factor to produce the disease.

Any theory proposed as a solution to the causation of AS must also explain why individuals possessing particular antigens, such as HLA-B27, have a greater chance of developing the disease. Currently two main theories have been proposed to explain the association of HLA-B27 with AS. The two theories are the receptor theory and the molecular mimicry theory.

The receptor theory states that the HLA-B27 molecule acts as a receptor cavity for some, as yet undefined, external polypeptide, which then somehow increases the susceptibility to develop the disease. No such polypeptide has yet been described. Until such a polypeptide is identified, the validity of the receptor theory will remain untested. The molecular mimicry theory is so far the only theory that has provided a

specific etiological agent which may be involved in the causation of AS.

Molecular mimicry and AS

The molecular mimicry theory states that the HLA antigen has a sequence that resembles biochemically and immunologically a similar sequence, located in

some environmental agent, such as a bacterium or a virus. The molecular mimicry model was first proposed by Ebringer, in 1976, at the HLA and Disease Congress, which was held in Paris. Sera obtained from rabbits immunized with HLA-B27-positive lymphocytes reacted with a number of gram-negative bacteria, such as *Klebsiella*, *Enterobacter*, *Salmon-*

ella and *Yersinia*. A search for these microbes in fecal samples obtained from AS patients during active phases of the disease revealed that only *Klebsiella* could be isolated from such patients.

In 1980, Avakian and coworkers reported that allogeneic, anti-HLA-B27 tissue typing sera showed increased binding for *Klebsiella* antigens using three different techniques: radiobinding assay, radioimmunoassay and hemagglutination. Van Bohemen later showed that an anti-HLA-B27 monoclonal antibody (M1), produced by Grumet, reacted with *Klebsiella*, *Shigella* and *Yersinia* strains. Kono and coworkers described an anti-*Yersinia* monoclonal antibody which reacted with 12 out of 12 B27-positive lymphoblastoid cell lines, but with only 4 out of 31 B27-negative ones. However, three out of the four reactive B27-negative cell lines carried HLA-B7, an antigen that crossreacts with HLA-B27. They then went on to show that a second anti-HLA-B27 monoclonal antibody (M2), again produced by Grumet, bound specifically to a 70 kDa component of *Klebsiella*, while no such reactivity was demonstrated by five other monoclonal antibodies. In 1987, Schwimmbeck, Yu and Oldstone identified a hexamer sequence, Gln-Thr-Asp-Arg-Glu-Arg (QTDRED), which was present in amino acid residues spanning positions 188–193 of the nitrogenase enzyme found in *Klebsiella pneumoniae* and the same sequence also occurs on the outer lip of the $\alpha 1$ domain of the main Caucasian HLA-B27 molecule. Furthermore antibodies to this shared sequence were found in the sera of AS patients.

Fielder and coworkers, in 1995, identified a second molecular complex in *Klebsiella* microorganisms which showed crossreactivity with self tissues. Molecular mimicry was shown to be present between two sequences of *Klebsiella pneumoniae*: pulD secretion protein (DRDE) with HLA-B27 and pulA (pullulanase) enzyme (Gly-X-Pro) with types I, III and IV collagen respectively (Figure 1). Furthermore, antibodies to both pullulanase and types I and IV collagen were observed in AS but not rheumatoid arthritis patients when compared with controls. It is relevant to note that type I collagen is present predominantly in tendons and bone. Antibodies cross-reacting between pulA and type I collagen could explain the deposition of fibrous tissue in the axial skeleton, thereby accounting for the main pathological feature of this disease, namely its spinal manifestations. Type IV collagen has been reported to be present in the basement membrane of uveal tissues but it remains to be determined whether crossreactivity with *Klebsiella* pulA is involved in the uveitis found in AS patients.

The molecular mimicry between HLA-B27 and

Klebsiella bacteria isolated from AS patients has been defined down to the level of similarity of four amino acids, found in both the suspect bacteria involving two separate molecules and the genetically susceptible population. Thus the term 'molecular mimicry' could not be said to be inappropriate when studying crossreactivity between bacterial antigens and HLA molecules. Since both the bacteria and antibodies to the bacteria have been demonstrated in AS patients, maybe molecular mimicry could provide a pathogenetic model for the causation of the disease.

Molecular mimicry and pathology of AS

The identification of a shared tetramer sequence between HLA-B27 and *Klebsiella* has confirmed the molecular mimicry model.

If there is crossreactivity between HLA antigens and bacteria, then infection by such microorganisms will lead to the production of antibodies, which will have both antimicrobial as well as anti-self or autoimmune activity. Only a small proportion of the subset of the antimicrobial antibodies will also have anti-self or autoimmune activity. Those bacterial antigens carrying the shared sequences will be immunogenic, especially around the edges of the shared sequence, because it is at these sites that the immune system will not recognize that it is dealing with a self antigen.

If, for example, the bacterial shared sequence is spanning residues 188–193 of the nitrogenase molecule, then the edge antigenic pentamer 187–188–189–190–191 will not be recognized as a self antigen because of the haptenic effect of the nonself amino acid at position 187, and yet the antibody produced may well bind to HLA-B27.

When present in sufficient quantities, such antibodies might activate the complement cascade and cause cytotoxic death with consequent stimulation of the inflammatory cascades, which will eventually result in localized tissue damage. There is thus no breakdown of tolerance and the evocation of bacterial antibodies having also anti-self or autoimmune activity is part of the normal immune response when encountering partially crossreacting antigens.

A classical example of this process, where one haptenic amino acid can cause autoimmune disease, is shown by autoimmune hemolytic anemia, which occurs in hypertensive patients treated with α -methyldopa. Yet the process is not self-sustaining, because once the drug is withdrawn the autoimmune hemolytic anemia subsides. A similar mechanism may be considered to occur in AS and the pathogenetic process can be illustrated as follows:

1. *Infection* occurs in the ileum and ascending

Figure 2 Comparison of space-filling models. (A) ESRRAL sequence of *Proteus mirabilis* hemolysin predicted from known crystallographic structure; (B) EQRRAA sequence within DRB1*0101 (HLA-DR1), predicted from known crystallographic structure; (C) EDERAA sequence of DRB1*0402 (HLA-DR4/Dw10); (D) predicted LRREI sequence of $\alpha 2(XI)$ collagen; (E) predicted IRRET sequence of *Proteus mirabilis* urease. (Reproduced with permission from Wilson *et al* (1995). Molecular modelling by Dr C Ettelaie.)

colon, where the bacteria replicate; their quantity will depend on the dietary intake of the patient. Elegant ileocolonoscopy studies by Mielants have shown that over 50% of active AS patients have histological evidence of gut inflammation. This infection is at a different site

from the eventual location of the arthritic lesions in AS.

2. *Antibody* against *Klebsiella* is produced in the lymph nodes draining the lower ileum and colon; the nodes are located in the mesentery which is attached to the anterior aspect of the lumbar

spine and sacroiliac joints. Elevated levels of antibodies to *Klebsiella* and to no other bacteria were first reported by Trull and coworkers and subsequently confirmed by other groups. Thus a high concentration of anti-*Klebsiella* antibodies is being produced by lymph nodes that are anatomically or geographically located near the main pathological sites in AS, namely the lumbar spine and sacroiliac joints. A subset of these antibodies will bind to cells carrying HLA-B27.

3. *Inflammation* will be triggered by those anti-*Klebsiella* antibodies binding to HLA-B27 molecules and, because of complement activation, cell death and tissue damage will occur. The end-result of inflammation is fibrosis and this is the main pathological lesion of AS.
4. *Chronic disease* will supervene because repeated cycles of infection will produce recurrent waves of anti-*Klebsiella* antibodies, which will cause tissue damage. Eventually this will manifest itself as a generalized fibrosis around the lumbar spine and we call this disease 'ankylosing spondylitis'.

Is there any evidence which suggests that the pathological processes in AS occur through such a molecular mimicry mechanism? In 1989, Husby and coworkers showed that rat antisera raised against *Klebsiella* nitrogenase enzyme antigens containing the shared QTDRED hexamer reacted with 13 out of 14 synovial biopsies obtained from HLA-B27-positive AS patients but with none out of seven biopsies obtained from HLA-B27-negative individuals suffering from either rheumatoid arthritis or osteoarthritis.

The following year, Baines and coworkers showed that rabbit anti-*Klebsiella* sera bound to a greater extent to lymphocytes obtained from 30 B27-positive AS patients and 21 B27-positive healthy controls compared with the binding by lymphocytes from 37 B27-negative healthy controls. Finally, Ewing and coworkers demonstrated, using synthetic peptides, that higher antibody activity was found around the edges of the shared hexamer sequence.

Since anti-*Klebsiella* antibodies are found in AS patients and since xenogeneic anti-*Klebsiella* antibodies bind preferentially to HLA-B27-positive cells, it is not too speculative to suggest that in the presence of high antibody titers the characteristic lesions of AS may arise. One obvious way of testing this theory is to eliminate the antibacterial antibodies and determine whether further pathological damage can be stopped.

Rheumatoid arthritis

Rheumatoid arthritis (RA) is a chronic inflammatory arthritis affecting predominantly the hands and feet but it can involve almost any joint. The mean age of onset is later than in AS, usually in the forties, but it can occur at any age. It is three times as common in women as men and any model proposed to explain this disease must account for this characteristic feature.

RA occurs predominantly in individuals carrying HLA-DR1, some subtypes of HLA-DR4 (DW4, DW14 and DW15) and HLA-DR6 (DW16), but not in individuals carrying some other HLA-DR4 subtypes (DW10 and DW13). An examination of these susceptible HLA sequences demonstrated that the common denominator was the sequence QRRAA, present on the DR β 1 chain, encoding positions 70–74. The sequence closely resembles that found in HLA-DR4(DW4) individuals where there is a conservative substitution at position 71 from arginine to lysine.

In 1992, Ebringer and coworkers showed that there was molecular mimicry between the RA 'susceptibility sequence' EQRRAA and the sequence ESRRAL found in *Proteus* hemolysin. Furthermore, elevated titers of specific antibodies to *Proteus mirabilis* in RA patients have been demonstrated by several groups. Wilson and coworkers went on to show that two separate sequences of *Proteus mirabilis* showed molecular mimicry with human self antigens: ESRRAL of *Proteus* hemolysin with EQRRAA of the HLA-DR1/DR4 susceptibility sequence and IRRET of *Proteus* urease (positions 337–341) with LRREI of α 2 chain of type XI collagen (positions 421–425) (Figure 2). Type XI collagen is a component of hyaline cartilage frequently found in small joints and since erosions are a common characteristic of this disease, it could explain the anatomical locations of these lesions. Furthermore, specific antibodies were found, in RA patients, against the ESRRAL sequence of the susceptibility sequence DR1/DR4 but not against the EDERAA sequence found in HLA-DR4(DW10), a subtype not associated with this disease. Finally, RA patients had elevated titers of specific antibodies to purified *Proteus* hemolysin and urease when compared with AS patients and healthy controls. In a coded study involving 89 subjects, Wilson and coworkers found that *Proteus* could be isolated more frequently from the urine of RA patients attending an outpatient clinic compared with controls. A correlation was found between the anti-*Proteus* antibody titer and the number of colony-forming units grown from the urine specimens.

By 1997, specific elevations of anti-*Proteus* antibodies had been reported from ten different countries throughout the world and the perception was emerging that this microbe is a strong candidate for the etiological agent of this severe arthritic condition.

Conclusion

Molecular mimicry has been defined down to the level of shared carbohydrate and amino acid residues in three important diseases: rheumatic fever, ankylosing spondylitis and rheumatoid arthritis. It is possible that a similar mechanism may operate in other human and animal diseases.

MONOCLONAL ANTIBODIES (mAbs)

Ailsa M Campbell, Institute of Biomedical and Life Sciences, Davidson Building, University of Glasgow, Glasgow, UK

Polyclonal antiserum raised against any individual molecular antigen consists of an assortment of antibodies of a variety of classes binding to different epitopes on the antigen with a diverse range of affinities, the proportion varying from animal to animal and within the one animal from bleed to bleed. In monoclonal antibody (mAb) production, the cell producing a single one of these antibodies is selected and propagated in large amounts. This gives a standard reagent

available indefinitely in large quantities. The cell line which makes such an antibody is called a B cell hybridoma. The relevant techniques are conceptually simple and involve the fusion of a B lymphocyte secreting antibody of the desired specificity with a myeloma (plasmacytoma) line which has the capacity for indefinite growth and division. The resultant hybrid then carries the antibody-secreting capacity of one parent and the immortality of the other.

The first production of monoclonal antibodies was reported by Kohler and Milstein in 1975 and led to the award of the 1984 Nobel Prize to these two scientists together with Neils Jerne.

Methods of making monoclonal antibodies

General

While the generation of a mAb is a fairly simple process, the generation of a useful one is often more complex. The fusion process itself takes only a few minutes and involves the incubation of the two types of cell together with a fusogen which is generally polyethylene glycol (PEG) (Figure 1). Hybrids which secrete antibodies of the desired specificity are detected by screening assays that are as close as possible to the final anticipated application of the antibody, although if this is to be a complex application such as *in vivo* use fully relevant screening is not possible.

Cells to be fused

The main requirements for the generation of a good monoclonal antibody are 1) a source of large numbers of suitably activated B lymphocytes from a hyperimmune subject and 2) a fusion partner from (ideally) the same species which is immortal and which has plasmacytoma/myeloma characteristics, i.e. a well-developed endoplasmic reticulum and the capacity to make large amounts of the required antibody after fusion, but which lacks the capacity to make antibody coded by its own genes. This last point is important since otherwise the fused cells make not only antibody from both parents, but also hybrid antibodies involving the combination of the different chains of the two and the capacity of the fused cells to make the required monoclonal in large amounts is corrupted.

The fusion partner must also be made sensitive to a drug such as aminopterin or azaserine so that those cells which do not acquire the drug resistance genes by fusion can be eliminated; this is a comparatively simple process.

In rodent systems the above conditions are fairly readily achieved. The spleen from a hyperimmune animal is probably the best source of B lymphocytes and nonsecreting, drug-sensitive myeloma lines of high fusion efficiency from both the mouse and rat are readily available. In the BALB/c mouse, the most commonly used cell lines are the P3-X63-Ag8 6.5.3 and Sp2/0 cell lines and in the rat the Lou Y3 Ag 1.2.3 line is the most successful (although this retains the capacity to make a kappa light chain). Lympho-

cytes from the Armenian or Syrian hamster can also be fused with mouse myeloma lines to yield stable hybrids.

A small number of groups have been working on generating monoclonal antibodies from bovine, ovine or rabbit sources in more recent years but the rodent systems remain dominant.

Selection and cloning

After fusion, the cells are grown in selective medium. The usual medium for rodent fusions is hypoxanthine, aminopterin and thymidine (HAT). Only cells which have the enzyme hypoxanthine phosphoribosyl transferase (HPRT) and thymidine kinase (TK) can grow in this medium, and the myeloma cells, which have been selected to lack one of these two enzyme activities, therefore die if they have not acquired them by fusion. Spleen cells generally only survive for 10–14 days in culture and thus only the hybrid fused cells survive.

Small clones of hybridomas emerge from the debris of the dead spleen and myeloma cells 5–20 days after the fusion and are assayed to detect those which make antibody of the required specificity. These are then cloned on feeder cells at a density of one hybridoma cell per well in 96-well tissue culture plates so that the final antibody is indeed monoclonal and that the cell secreting it is stable. The antibody-producing cells can then be grown in bulk in the ascitic fluid of rodents or in large culture vessels depending on the quality and quantity required. Antibody purification from the other components of the culture medium is accomplished by standard biochemical or immunochemical purification systems.

Methods for generating human monoclonal antibodies

Human monoclonal antibodies are required for most therapeutic uses as rodent ones are immunogenic and thus ultimately ineffective in humans. They have, however, proved difficult to generate, mainly because it is usually not possible for ethical reasons to hyperimmunize human subjects and frequently the only available source of B lymphocytes is peripheral blood in which the state of activation of the cells is less suitable for fusion.

There are three main ways in which this problem may be overcome (Figure 2):

- (a) A conventional mouse hybridoma is made from an ordinary hyperimmunized BALB/c mouse, and the antibody-coding genes are then manipulated so that the constant regions are of human rather than murine origin. A further sophistication of this technique is to also 'humanize' the

Figure 1 Methods of producing a monoclonal antibody.

Figure 2 Strategies for generating a human monoclonal antibody. (A) From a conventional mouse hybridoma by manipulation of its constant region genes. (B) From a transgenic mouse carrying human immunoglobulin genes. (C) Transformation by Epstein-Barr virus. Note that in (A) and (B) the response reflects that of the mouse to a human antigen, whereas in (C) the human response to self-antigens (e.g. rhesus, autoantigens) is immortalized.

framework regions of the mouse antibody leaving only the CDRs (complementarity determining regions) of murine origin. Such antibodies elicit little or no immune response in humans.

- (b) A genetically engineered mouse is hyperimmunized. Originally, the SCID (severe combined immunodeficiency) mouse was used as it could be, to some extent, populated with an artificial human immune system. More recently, two groups have produced mice with parts of the murine heavy and light chain immunoglobulin loci replaced by the human loci. Such mice, when hyperimmunized, produce murine B lymphocytes making human antibodies and these can then be used in a normal mouse fusion yielding a murine hybridoma making human antibodies.
- (c) Use of Epstein-Barr virus (EBV) to immortalize human B lymphocytes which carry its CD21 receptor. This is the only method which gives hybridomas making a genuine human response to human antigens, as strategies (1) and (2) immortalize the murine response to the antigen. Clearly the mouse immune system may see many foreign determinants on a human cellular antigen and these may mask its response to the single antigen that the human immune system sees as foreign. The most obvious example is the rhesus blood group antigens which are masked in the mouse by its response to the human ABO system but which are strong antigens in humans. The EBV method can also be used to interrogate the antibody profile and V gene usage in autoimmune conditions by immortalizing the B lymphocytes present at the site of the

lesion. EBV transformants grow well but tend to cease antibody secretion unless this is stabilized. They are therefore frequently 'backfused' after initial cloning to a more stably secreting myeloma line, frequently of mouse origin. The resultant antibody remains human.

Alternative recombinant methods

Newer recombinant methods involve the creation of gene expression libraries from (usually) immunized mice or humans. These may contain the variable regions, or variable plus partial constant region of the heavy or light immunoglobulin chains, and Fab libraries from a combination of the two. A very large number of clones can be screened by inexpensive filter binding methods. In addition, the antibodies can be expressed on the surface of filamentous DNA bacteriophage and selected by affinity chromatography on antigen.

Properties of monoclonal antibodies

Affinity and specificity

Among the most important properties of monoclonal antibodies are their defined nature and their availability over indefinite periods of time. Monoclonal antibodies can also be reagents of exquisite specificity with the ability to identify small amounts of antigen in complex mixtures, giving very low background staining in diagnostic systems. However, they cannot necessarily be assumed to have such properties and it is wise to obtain as much information as possible about the systems in which any mAb has been characterized before using it. Many

commercially available mAbs are poorly characterized and appear to have been bought in by some firms more to swell their catalog repertoire than to offer a useful reagent. In general, a good mAb should have a high intrinsic affinity for the chosen antigen. This means that mAbs of the immunoglobulin M (IgM) class, which have high avidity but often low intrinsic affinity, should be avoided in most cases, the exceptions possibly being in ABO blood grouping where agglutinating IgM mAbs tend to be employed and are well-characterized for use in the specific diagnostic systems employed.

Potential cross-reactions

Monoclonal antibodies can cross-react in two different ways. The first is the expected one where two dissimilar antigens have elements of structural identity. For example, a mAb to lactate dehydrogenase will obviously cross-react with isocitrate dehydrogenase if its epitope is at the common nicotinamide adenine dinucleotide (NAD)-binding site but will not do so if its epitope is at the lactate-binding site. This type of cross-reaction can be investigated at an early stage in screening and the desired antibody can be selected. The second type of cross-reaction is more difficult to detect at early stages of mAb production. This is where a mAb can bind to two or more totally dissimilar antigens, probably using different amino acids in the CDRs, although for steric reasons, it usually cannot bind both at the same time. Antibodies which do this tend to be of the IgM class with low intrinsic affinity for either antigen and this is why such antibodies should be avoided where possible. The phenomenon is particularly evident with polyvalent antigens such as single-stranded DNA and intracellular structural proteins and also where antigen has been plated at high density on an ELISA plate, thus driving a low-affinity interaction forward to give a positive result. Clearly, since these cross-reactions occur with molecules dissimilar to the selecting antigen they are difficult to identify on screening but it is important to try to do so. For example if a mAb selected to bind to a tumor cell for *in vivo* use has even a very low additional capacity to bind to, say, collagen or some other abundant body protein, it is likely to be diverted in its clinical application. While there is a view that such polyspecific antibodies are only secreted by certain types of B lymphocyte expressing the CD5 marker, polyspecificity is a potential feature of any antibody with low intrinsic affinity for the selecting antigen.

It is also possible for monoclonal antibodies to be overspecific in, for example, diagnosis of microbial antigens where a single mAb may only detect a parti-

cular serotype. For this reason, selected mAbs are often pooled to make a comprehensive diagnostic kit.

Diagnostic applications of monoclonal antibodies

In immunological research

Monoclonal antibodies have had wide application in both basic and applied immunological research. For the former, the reader should refer to the cluster of differentiation (CD) system, which is entirely defined by mAbs and now encompasses more than 200 cell surface markers, to appreciate the immense value of mAbs in identifying phenotype, developmental stage and activation status of cells of the immune system. In combination with flow cytometric analysis (FACS) these CD-specific mAbs can be used to detect the appearance or absence of cell populations during antigenic stimulus or infection, for example in monitoring the decline of CD4⁺ cells during the progression of AIDS (acquired immune deficiency syndrome) infection, or the increases in cell surface density of lymphokine receptors during lymphocyte activation.

In general

Monoclonal antibodies are now extensively used in diagnosis in many fields and the estimated annual world market is in excess of US\$3 billion. In most cases, the double sandwich mAb technique where a mAb directed to one part of the antigen under test is used to 'capture' it and a mAb to a different epitope, linked to a detecting system is used to provide the signal has overtaken radioimmunoassay. Diagnostic kits utilizing mAbs for the detection of human chorionic gonadotropin (hCG) in pregnancy or luteinizing hormone (LH) during ovulation are generally available and other home diagnostic kits for bacterial infections including streptococcal infections of the throat and venereal disease have been developed, although these are not on general sale in most countries.

Most mAb-based kits utilize a color reaction as the final detection system but these can readily be adapted by luminescent or bioelectronic mechanisms to biosensors which can beep, flash or trigger mechanisms which generate further intervention without direct human involvement in the relevant decisions. Such systems may prove of value in continuous monitoring of environmental hazards or in process control during, for example, large-scale production of antibiotics.

In the standard laboratory environment, mAbs are now routinely used to determine ABO blood group

antigens and blood and tissue levels of protein and polypeptide hormones. The diagnostic market has, however, been modified over the last decade by the development of routine polymerase chain reaction (PCR) facilities in most laboratories. PCR is very much more sensitive than immunological methods for techniques such as HLA typing and pathogen diagnosis.

Therapeutic applications of monoclonal antibodies

General

Monoclonal antibodies have not yet realized the optimistic expectations of the last two decades in terms of therapy. Scientific understanding of most human diseases has also developed significantly during this period, as has conventional pharmacology, so that monoclonal antibody therapy no longer appears to be appropriate for many of the major diseases in comparison to smaller, cheaper, drug molecules which can more readily penetrate tissues and intracellular compartments.

Transplant rejection/autoimmune disease

The first monoclonal antibody to be licensed by the Food and Drug Administration (FDA) for therapeutic use in humans was OKT3, a mouse antibody which targets all T cells through the cell surface CD3 complex. It is used in acute allograft rejection only where conventional immunosuppressive drugs such as cyclosporine and FK506 have failed, and its cost is very much greater than either of these drugs. Rejection of this foreign mouse antibody is rare since it functions to immunosuppress the patient.

In the case of autoimmune disease which is generally not life threatening, such drastic measures are usually inappropriate and much interest has centered on the removal of specific compartments of the immune system to downregulate the autoimmune response without destroying that patient's ability to fight routine infections. Monoclonal antibodies to CD2, CD5, CD7 and CDw52 have all been put through preliminary clinical trials, as have antibodies to various cytokines and their receptors, but no clear candidate therapy has emerged and for any that may do so, the cost per patient will be a relevant issue.

Bacterial infections

Extracellular bacteria and bacterial endotoxins are the natural target for antibodies and consequently mAbs should have an ideal therapeutic application in such cases. However, low-cost antibiotics are available for the treatment of the great majority of

bacterial disorders so that mAbs cannot compete. Such drug resistance as occurs tends to be in the poorer communities where mAb therapy is not within accessible cost range.

The lipopolysaccharide (LPS) endotoxins, however, provide a potential target since these are the causative agents of gram-negative sepsis in burns and postoperative patients in developed nations and the condition is often fatal before the host antibody immune response has developed. Gram-negative sepsis is caused by a wide range of bacteria, all of which have the lipid A component in common in their LPS endotoxins. Two antibodies, one human IgM and the other murine IgG, both claimed to be specific to Lipid A, and thus all gram-negative endotoxins, were developed for this purpose by two different companies in the late 1980s. Lipids are poor antigens and it remains possible that such antibodies had multiple specificities to the highly antigenic carbohydrate moiety of the LPS. Clinical trials gave ambivalent results, with neither antibody being commercially successful to date. The best reagent would almost certainly be a human IgG antibody to lipid A which could readily be produced by modern technology.

Tumor therapy

In the early days of mAb development, it was anticipated that the potentially high specificity of mAbs would mean that they could be employed not only to identify small metastatic populations of tumor cells but also to kill them, either alone or in conjunction with a cytopathic agent, while leaving normal cells unharmed. This hope has largely not yet been realized and indeed many of the claims of tumor-associated epitopes defined by mAbs in the early 1980s remain unsubstantiated. There are several reasons for this lack of success. For example, the major tumors of humans are those of the epithelial cells of the colon, breast, lung and prostate, and it is now clear that many of the oncogenes activated within such cells code largely for intracellular proteins which are inaccessible to antibody therapy. This view is strengthened by the fact that such common tumors show no increase in frequency in immunosuppressed individuals. Chemotherapeutic strategies have, meanwhile, advanced considerably and offer more chance of success at lower cost in many of these tumors.

In the case of tumors of the immune system, the situation is slightly different. Tumor-specific idiotypic markers are identifiable in B cell lymphomas and the CD antigen surface characteristics of any group of tumor cells may also be used as a mAb target. Uniquely, in the hematopoietic and immune system, it is possible to consider the use of

mAbs temporarily to eliminate all populations other than stem cells with consequent eradication of the bulk of the tumor cells and their clonogenic precursors carrying the activated oncogene. Therapeutic strategies using human–rodent chimeric mAbs have been directed towards this goal for some years now with limited success, perhaps because the originating cell is closer to the hematopoietic stem cell than the one which bears the targeted antigen. Further immunological research may uncover more appropriate targets.

It is possible that, as in many of the diagnostic systems where mAbs are now pooled to form a highly defined polyclonal reagent, or where multi-drug therapy is common in many cancers, antibody-based tumor diagnosis and therapy may also require a pool of antibodies to different epitopes for optimal effect.

Other applications

These tend to encompass improvements in technology achieved by transfer of experimental systems from polyclonal to monoclonal application and include, for example, catalytic mAbs which perform

reactions for which there is no natural enzyme system, albeit at low efficiency as yet, and the use of mAbs in antigen purification.

MONOCYTE CHEMOATTRACTANT PROTEIN 1 (MCP-1)

Claus OC Zachariae, Christian G Larsen and Kouji Matsushima, Department of Haematology, Herlev Hospital, University of Copenhagen, Denmark

Monocyte chemoattractant protein 1 (MCP-1) is encoded by human chromosome 17q11.2–q21.1 and is also known as MCAF (monocyte chemotactic and activating factor). MCP-1 belongs to the chemokine β family as it has a C–C (cysteine–cysteine) amino acid sequence, as opposed to the C–X–C structure of the chemokine α family to which interleukin-8 (IL-8) belongs. The most prominent features of MCP-1 are its chemotactic effect towards monocytes *in vivo* and *in vitro* and its activating effect on monocytes.

MCP-1 shows 21% amino acid sequence homology to IL-8. There is about 55% homology between the human MCP-1 and the murine JE analog. MCP-1 is produced from a 99 amino acid precursor to yield a 76 amino acid mature form. The MCP-1 receptor (CCR2A, CCR2B) is a seven transmembrane-spanning G protein-coupled molecule of 39 kDa with homology to other chemokine recep-

Downregulation

The production of MCP-1 is suppressed by the following agents:

Glucocorticoids
17 β -Estradiol (E₂)
IL-10

tors. The CCR2B is also an HIV coreceptor, allowing fusion between the cell membrane and the HIV virus. A number of different cell types, both normal and malignant, can produce MCP-1 (Table 1). MCP-1 mRNA expression is induced within 30 min by IL-1 and tumor necrosis factor α (TNF α). A number of other factors may also induce MCP-1 production (Table 2), including MCP-1 itself, other proinflammatory cytokines, growth factors, mitogens, bacterial products, viruses and immunoglobulin G (IgG) complexes. MCP-1 production is inhibited by steroids and IL-10.

MCP-1 was initially identified because of its chemotactic effect towards monocytes. Apart from chemotaxis it also induces other events in monocytes such as enzyme release, increased expression of

β_2 -integrin cell adhesion molecules, as well as augmentation of monocyte cytostatic activity against several malignant cell lines (Table 3). Injection of MCP-1 subcutaneously into the ears of rats induces considerable monocyte infiltration, beginning at 6 h and peaking by 16 h. Additionally, MCP-1 degranulates dermal mast cells upon injection into mice. The related molecules MCP-2 and MCP-3 are also monocyte chemotactic.

It has been shown that murine tumors producing JE contain a greater number of tumor-associated macrophages and that the animals have a better

prognosis than animals with tumors not producing MCP-1. This, along with its capacity to activate monocytes, suggests a role for MCP-1 in tumor growth control. Evidence for an inflammatory role of MCP-1 is mainly circumstantial. Thus the detection of MCP-1 in several disease states indicates a possible role in infectious, autoimmune and malignant conditions (Table 4). MCP-1 is also assumed to play a significant pathophysiologic role in atherosclerosis, where the chemokine is produced by endothelial cells stimulated with oxidized low-density lipoprotein (LDL).

MONOCYTES

Ralph van Furth, Laan van Oud Poelgeest, Oegstgeest, The Netherlands

Henry Beekhuizen, Department of Infectious Diseases, University Hospital, Leiden, The Netherlands

Monocytes are phagocytic cells that belong to the mononuclear phagocyte system and reside in the circulation before they enter the tissues where they differentiate into macrophages. Human monocytes in circulation have a diameter varying from about 10 to 18 μm ; the surface possesses microvilli and an undulating membrane. The heterogeneity in size may be explained by differences in maturation stage and/or activation state. The cytoplasm of monocytes contains a small number of granules, designated as primary lysosomes, a Golgi complex, rough endoplasmic reticulum, and mitochondria. The eccentrically placed nucleus is indented or reniform and generally contains one or two small nucleoli. The main contents of the lysosomes are acid phosphatase, peroxidase, lysozyme, neutral proteases, elastase and collagenase. Monocytes may play a central role in

host defense because of their capacity to process and present antigen to T lymphocytes, their regulatory function through the secretion of biologically active molecules, their tumoricidal and antimicrobial activities.

Origin and kinetics

Monocytes originate in the bone marrow from pluripotent stem cells; their direct precursor cell is the promonocyte that derives from the monoblast. After monocytes are formed by division of promonocytes, they remain only a very short time (less than a day) in the bone marrow compartment. When monocytes enter the circulation they are divided over a circulating pool and a marginating pool, each comprising about 50% of the monocytes present in the blood

vessels. Monocytes stay for a relatively long time in the circulation, the half-life being 17 h (mice) to 71 h (humans). Then they leave this compartment randomly by a process called diapedesis (see below) and migrate to tissues and body cavities where they differentiate into macrophages. The production of monocytes in the bone marrow is governed by growth-stimulating cytokines such as interleukin 3 (IL-3), stem cell factor (SCF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and macrophage colony-stimulating factor (M-CSF), and during inflammation also by factor increasing monocytopoiesis (FIM). As a consequence, the number of monocytes in the peripheral blood increases by 1½–2 times, the half-life of monocytes in the circulation is temporarily reduced to about 12 h, and the majority of this increased number of monocytes migrate to the site of inflammation.

Treatment with glucocorticosteroids decreases the number of circulating monocytes and high doses result in complete monocytopenia. When this occurs during inflammation the number of monocytes available to migrate to the site of the lesion is reduced and consequently the number of (exudate) macrophages in the inflammatory exudate is rather small. The decrease in monocytes in the peripheral blood is caused by decreased production in the bone marrow, by delayed migration of monocytes from the bone marrow into the circulation and by temporary margination of these cells in the circulation, but not by destruction of monocytes.

Functions

Monocytes should be considered to be in transport from their site of origin to the site of function, i.e. the tissues and body cavities. In the tissues, monocytes differentiate first into exudate macrophages, which still have many characteristics of monocytes, and then into resident macrophages. It is not known what functions monocytes exert when they reside in the circulation. The following summary concerns the functional abilities of monocytes and monocyte-

derived (exudate) macrophages when these cells are studied *in vitro*.

Monocytes are well equipped to ingest opsonized microorganisms, red blood cells and other materials. The process of phagocytosis can be divided into a series of stages. First, the (opsonized) particles attach to the surface of the phagocyte. The opsonins serve as ligands for the binding of the particles to specific receptors on the surface of the monocytes; nonopsonized microorganisms and other cells can also bind by sugars in their cell surface to lectin-like receptors on monocytes. After ligation of the particle to the cell surface, a signal is generated that promotes the internalization process. Pseudopods of the cell advance by assembly of actin filaments that reach the membrane and form a network in the pseudopods. The pseudopods adhere closely to the particle by interaction of the ligand with the receptors on the cell surface. This process is called the zipper mechanism (Figure 1). When the engulfment is completed the particle resides in the cytoplasm in a vacuole, which is formed by the inverted cell membrane, and called a phagosome. Next lysosomes fuse with the phagosome and lysosomal enzymes are released into the phagosome and come in contact with the phagocytosed particle. The following step in this process is that microbicidal mechanisms and digestive processes come into operation.

The antimicrobial functions of monocytes are mediated by oxygen-dependent and oxygen-independent mechanisms. The respiratory burst that accompanies phagocytosis leads to the formation of reactive oxygen metabolites including superoxide anion (O_2^-) and hydrogen peroxide (H_2O_2). After fusion of the phagosome with granules that contain peroxidase, this enzyme together with H_2O_2 and a halide, such as chloride, forms HOCl, a hypochlorite with microbicidal activities. In mice, but not in humans, (exudate) macrophages form nitric oxide, which may be involved in antimicrobial activities of these cells. The oxygen-independent antimicrobial mechanisms of monocytes and (exudate)

Figure 1 Various stages of the phagocytosis process.

macrophages include vacuolar acidification, nutrient deprivation and the action of antimicrobial polypeptides. Monocytes and macrophages contain granule-associated polypeptides such as lysozyme, defensins (only in rabbit alveolar macrophages), serprocidins (i.e. cathepsin G, elastase, proteinase 3 and azurocidin), and histone-related murine microbicidal proteins (MUMPs). The cytosol of macrophages contains a small, cationic, antimicrobial protein, called ubiquicidin. During differentiation of monocytes into resident macrophages, the monocytes lose their peroxidase activity, which is accompanied by a decrease in antimicrobial activity. However, resident macrophages can become activated by various kinds of cytokine, for example, interferon γ (IFN γ) formed by CD4⁺ T lymphocytes and natural killer (NK) cells, and then regain microbicidal activities and acquire tumoristatic or tumoricidal characteristics.

Another important function of mononuclear phagocytes, especially of (exudate) macrophages and to a smaller degree of monocytes, is the secretion of biologically active substances. Some substances are formed and secreted constitutively and others only after activation of the cells. These secretory products can be divided into enzymes (e.g. elastase, collagenase, proteoglycan degrading enzyme, plasminogen activator, lysosomal acid hydrolases, angiotensin-converting enzyme, arginase), enzyme inhibitors (e.g. α_2 -macroglobulin, plasminogen activator inhibitor, α_1 -antitrypsin), arachidonic acid derivatives (e.g. prostaglandins, thromboxane), plasma proteins (e.g. complement components, coagulation factors, fibronectin, apoprotein E), and many cytokines regulating functions or growth of other cells (e.g. IL-1, IL-6, IL-8, IL-10 and IL-12, tumor necrosis factor α (TNF α), GM-CSF, angiogenesis factor, IFN γ). The repertoire of secretory products may depend on the degree of maturation and/or the state of activation of the cell, and/or its localization in the body. The existence of subsets of monocytes and macrophages that are specialized to form only one or a small number of secretory products is rather unlikely.

Membrane characteristics

A large number of biological activities of monocytes and macrophages are determined by specific molecules present on the surface membrane of these cells. Some of these molecules are receptors for immunoglobulins (i.e. Fc receptors), cytokines, growth factors or plasmaproteins (e.g. complement or coagulation factors); others serve as adhesion molecules and regulate the interaction with subcellular matrix components or with other cells. During differen-

tiation or activation of monocytes the expression pattern of these receptors changes constantly.

Monocyte receptors for immunoglobulins

Human monocytes express receptors for the Fc region of immunoglobulin G (IgG), namely Fc γ receptor I (Fc γ RI; CD64), Fc γ receptor II (Fc γ RII; CD32) and, after *in vitro* culture, Fc γ receptor III (Fc γ RIII; CD16). Fc γ RI binds monomeric human IgG with high affinity, but also cross-reacts with murine IgG. The number of Fc γ RI molecules expressed on the plasma membrane of human monocytes is about $2-4 \times 10^4$ and increases about 2 to 4-fold upon differentiation into macrophages or stimulation with IFN γ . Fc γ RII on monocytes expresses polymorphism and binds human IgG only in its polymeric or complexed form with relatively low affinity. The number of Fc γ RII on monocytes is generally higher than that of Fc γ RI. There are two forms of Fc γ RIII: the transmembrane form, Fc γ RIIIA on monocytes, macrophages and NK cells, which binds human IgG with medium affinity, and the glycosylphosphatidylinositol (GPI)-linked form, Fc γ RIIIB, which is only expressed on neutrophils and interacts only with immune-complexed IgG. Only after *in vitro* culture monocytes express moderate quantities of Fc γ RIIIA.

IL-4-stimulated monocytes may express the low-affinity receptor for IgE, Fc ϵ RIIB (CD23). Furthermore, monocytes express a receptor for IgA, Fc α RI (CD89), which is a transmembrane glycoprotein that binds both isotypes of IgA. Fc α receptors on phagocytes exert their function mainly at the mucosal membranes where IgA antibodies are predominant. Fc γ receptors on monocytes play an important role in host defense against microbial infections. The attachment of the Fc region of IgG to the surface of monocytes via Fc γ receptors triggers a variety of cellular processes such as the internalization of small immune complexes (endocytosis), phagocytosis and intracellular killing of Ig-opsonized microorganisms and the secretion of inflammatory mediators.

Monocyte receptors for complement components

Components of the complement system enhance the antibacterial activity of monocytes and macrophages. This function is exerted by two important surface receptors for C3b, namely complement receptor type 1 (CR1; CD35) and complement receptor type 3 (CR3; CD11b/CD18). CR1 binds to the C3c region of C3b. CR3 is a heterodimeric protein that belongs to the β_2 subfamily of integrins, and is a receptor for C3bi. Both CR1 and CR3 are mediators in the phagocytosis of C3b- or C3bi-opsonized particles.

Monocyte receptors for adhesion

Monocytes express molecules which play a dominant or accessory role in the adhesion to platelets, lymphocytes and other cells, e.g. endothelial cells, or to a subcellular matrix. Based on functional and structural similarities, adhesion molecules on monocytes or macrophages are categorized in three distinct families: the immunoglobulin (Ig) superfamily, the selectins and the integrin molecules (see **Table 1**). Monocytes display several Ig superfamily molecules on their surface, namely the intercellular adhesion molecules (ICAM), platelet-endothelial cell adhesion molecule (PECAM), Fc γ receptors, leukocyte function antigen (LFA-3) and class I antigens, and after stimulation, class II major histocompatibility complex (MHC) antigens. These Ig superfamily glycoproteins play an important role in immunological processes including phagocytosis, antigen presentation and transendothelial migration.

L-selectin is the only selectin expressed on monocytes and to a much lesser extent on macrophages. The N₂-terminal Ca²⁺-dependent lectin-like domain of L-selectin is of importance in the initial attachment of monocytes to the vascular endothelium at inflammatory sites, which is an obligatory event before transendothelial migration can occur. Integrins on monocytes or macrophages belong to four different subfamilies, the β_1 -, β_2 -, β_3 - and β_5 -integrin subfamily, that can be distinguished based on the type of β chain that associates noncovalently with an α chain to form the functional heterodimeric molecule. The functional state of β_1 - and β_2 -integrins, in terms of their affinity for their ligands, is determined by the activation state of the cell. The β_1 -, β_3 - and β_5 -integrins on monocytes have been shown to interact with extracellular matrix components such as fibronectin, laminin or vitronectin, whereas β_1 - and β_2 -integrins mediate the interaction of monocytes or

Table 1 Major adhesion molecules expressed on human monocytes or macrophages

	Name	Subunits	Ligands
Integrins			
β_1 -integrins	VLA-2 (CD49b/CD29)	$\alpha_2\beta_1$	Collagen
	VLA-4 (CD49d/CD29)	$\alpha_4\beta_1$	VCAM-1, fibronectin
	VLA-5 (CD49e/CD29)	$\alpha_5\beta_1$	Fibronectin, <i>B. pertussis</i>
	VLA-6 (CD49f/CD29)	$\alpha_6\beta_1$	Laminin
β_2 -integrins	LFA-1 (CD11a/CD18)	$\alpha_L\beta_2$	ICAM-1, -2, -3
	CR3 (CD11b/CD18)	$\alpha_M\beta_2$	ICAM-1, C3bi, fibrinogen, Factor X
	p150,95 (CD11c/CD18)	$\alpha_X\beta_2$	C3bi, fibrinogen
	CD-/CD18	α_d/β_2	ICAM-3
β_3 -integrins	Vitronectin receptor (CD51/CD61)	$\alpha_V\beta_3$	Vitronectin, fibronectin, von Willebrand factor, Thrombospondin
β_5 -integrins	CD51/CD-	$\alpha_V\beta_5$	Vitronectin
Selectins	L-selectin (CD62L)		E-, P-Selectin, sialyl-Lewis ^x , CD34, MadCAM-1, GlyCAM-1
Ig supergene family	ICAM-1 (CD54)		LFA-1, CR3, rhinovirus, <i>P. falciparum</i>
	ICAM-2 (CD102)		LFA-1, CR3
	ICAM-3 (CD50)		LFA-1
	PECAM-1 (CD31)		PECAM-1, heparan sulfate, Proteoglycans, $\alpha_V\beta_3$ -integrin
	Fc γ RI, II and III (CD64, CD32 and CD16)		Fc region of IgG
	LFA-3 (CD58)		CD2
	MHC class I and II molecules		Processed foreign antigen
Noncategorized molecules	Leucosialin/sialophorin (CD43)		ICAM-1
	Sialoadhesin		Sialic acid-glycoproteins
	Hermes-1/Pgp-1 (CD44)		Hyaluronic acid, others
	Sialyl-Lewis ^x , sLe ^x (CD15s)		P-, E-, L-Selectin
	CD14		LPS/LPB, activated endothelium

macrophages with other cells, including lymphocytes and vascular endothelial cells. In the latter process members of the Ig supergene family may serve as excellent ligands for integrins.

Adhesion molecules in transendothelial emigration of monocytes

Under normal, noninflammatory conditions, a limited number of circulating monocytes adhere to and traverse the endothelial lining of the vessel wall. Under these conditions the efflux of monocytes from the circulation to the tissues ensures maintenance of the macrophage population in a given tissue compartment. During an inflammatory reaction, a variety of locally released inflammatory mediators, such as IL-1 α , TNF α , IFN γ , chemoattractants (e.g. anaphylatoxin C5a, leukotriene B₄), formylmethionyl peptides (e.g. fMLP), or chemokines (e.g. IL-8 or monocyte chemotactic protein-1 (MCP-1)), can modulate the adhesion of monocytes to endothelial cells. The increased adhesion of monocytes to the vascular endothelium and subsequent migration to the inflamed tissue satisfies the demand for macrophages at that site.

Intravital microscopy studies revealed that extravasation of monocytes, and of leukocytes in general, is preceded by a coordinated sequence of adhesion events that enables these cells to withstand the hemodynamic forces generated by the flow of blood and to make firm contact with the vascular endothelial cells. Three separate consecutive events can be distinguished: monocytes first attach to the vessel wall in a rolling interaction, next the cells are arrested and stick firmly to the surface of endothelial cells and thereafter transendothelial migration by diapedesis occurs.

Rolling of monocytes along the endothelial lining of small venules is observed exclusively at inflammatory sites or sites of vascular injury and *in vitro* under conditions of flow. Rolling involves short-lived attachment of monocytes via L-selectin to ligands such as P-selectin (CD62P), E-selectin (CD62E), or sialomucins (e.g. CD34, GlyCAM-1) on activated endothelial cells which is followed by detachment from the endothelium. Consequently the flow of monocytes in the main vasculature slows down. During rolling of the monocytes they become activated and enter the next phase of adhesion in which monocytes are arrested at a particular site of the vascular endothelium and migrate over the luminal surface of the endothelial cells.

The firm adhesion of monocytes to endothelium

relies primarily on the activation of β_2 -integrin molecules, resulting in an increase in affinity for their endothelial ligands (e.g. ICAM-1). However, also the β_1 -integrin VLA-4 and CD14 mediate firm adhesion of monocytes to activated endothelium. Activation of β_2 -integrins may be triggered by the chemokine MCP-1, which is produced by endothelial cells or elicited by binding of monocytes to the endothelial cell surface.

Monocytes finally cross the vessel wall by squeezing between tightly apposed endothelial cells in an ameboid fashion, called diapedesis, a process in which β_2 -integrin molecules are involved. This is concluded from the lack of neutrophil and monocyte diapedesis observed in patients with the leukocyte adhesion deficiency (LAD) syndrome, who are genetically deficient in the functional expression of leukocyte β_2 -integrin molecules. However besides β_2 -integrins, homophilic interaction of PECAM-1 on monocytes with PECAM-1 on the endothelial cells is also involved in transendothelial migration of monocytes.

Following diapedesis, monocytes attach to and subsequently traverse the subendothelial matrix, or basement membrane, consisting of fibronectin, laminin, collagen and sulfated proteoglycans, and enter the extravascular tissues.

MONONUCLEAR PHAGOCYTE SYSTEM

Ralph van Furth, Laan van Oued Palgeest 44, 2341 ML Oegstgeest, The Netherlands

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The similarities between the morphological, cytochemical, and functional characteristics of monoblasts, promonocytes, monocytes and macrophages, together called mononuclear phagocytes, combined with knowledge about the origin and kinetics of these cells, led to the concept of the mononuclear phagocyte system (MPS).

The origin of mononuclear phagocytes

During ontogeny, the hematopoietic stem cell – a cell of mesenchymal origin – arises in the yolk sac. In a later stage of gestation, these cells migrate to the fetal liver, where immature mononuclear phagocytes develop; hematopoiesis in the liver does not cease until term or the second week after birth, depending on the species. Soon after hematopoiesis begins in the fetal liver, monocytes appear in the circulation; only after that does hematopoiesis commence in the bone marrow. Before hematopoiesis commences in the bone marrow, osteoclasts formed by fusion of circulating mononuclear phagocytes (e.g. monocytes or younger cells of this cell line) are found in embryonic bone. The approximate time during gestation, when mononuclear phagocytes appear in hematopoietic organs and in the circulation of mouse and human, is shown in Table 1.

In adult life, mononuclear phagocytes are present in all tissues, but under normal conditions proliferating mononuclear phagocytes occur only in the bone marrow. The most immature cell of the mononuclear phagocyte cell line present in the bone marrow is the monoblast. This cell is derived from a granulocyte-monocyte progenitor cell which can be considered to be a committed stem cell that is derived from the multipotent hematopoietic stem cell. Division of the monoblast gives rise to two promonocytes, and the two daughter cells of a promonocyte are monocytes.

Thus, in the bone marrow from monoblast to monocytes, there is a cell amplification of four times. Monocytes remain in the bone marrow for only a short time (less than 24 h) and then enter the circulation, where they are present in a circulating or marginating pool. The marginating monocytes migrate through the endothelium of the vessel wall to the various tissues and body cavities. Adhesion molecules on monocytes and on endothelial cells, together with chemotatic factors, are involved in the migration of monocytes from the blood vessels into the tissues or body cavities.

In the extravascular tissues, monocytes transform into (exudate) macrophages. In the lungs, for example, monocytes differentiate directly into alveolar macrophages without maturation in the interstitium; in the sinusoids of the liver, monocytes become the Kupffer cells; and in the peritoneal cavity, monocytes arrive directly from the capillaries or via the milky spots in the omentum. In normal tissues, only a very small percentage of macrophages divide, these macrophages also having recently originated from the bone marrow. Little is known about the ultimate fate of the macrophages. Since there is no evidence that macrophages recirculate via the lymph vessels to the circulation, it seems likely that they die in the tissues where they reside or migrate to local lymph nodes.

Mononuclear phagocytes and inflammation

During an acute or chronic inflammation, the number of macrophages may increase and both the degree of the increase and the time at which it occurs are dependent on the nature of the stimulus and the type of tissue in which the inflammation occurs. Circulating monocytes are mainly responsible for the

Table 1 Ontogeny of mononuclear phagocytes

Site of formation of mononuclear phagocytes	Localization of mononuclear phagocytes at other sites	Time of gestation	
		Mouse	Human
Yolk sac		Days 7–12	Days 21–63
Fetal liver		Day 11 to 2nd week postnatal	5th week to term
	Circulating monocytes	After days 11–12	After weeks 7–8
	Osteoclasts	After day 15	After weeks 8–9
Bone marrow		At birth	After week 11

increase in the number of macrophages in the inflammatory exudate, and transitional forms between monocytes and resident macrophages are present in such exudates and are called exudate macrophages. There is also an increase of the number of dividing mononuclear phagocytes in an inflammatory exudate and in granulomas, due to the recruitment of immature mononuclear phagocytes from the bone marrow.

Alterations in the functional state of the (exudate) macrophages include their locomotion, chemotactic response, endocytic, microbicidal, cytostatic or cytotoxic activity, as well as their secretory state, their adherence to and spreading on a surface, and their cooperation with T and B lymphocytes. The inflammatory stimulus may act directly upon the macrophages and change their functional state, and such a change can also be mediated by cytokines secreted by lymphocytes or macrophages (i.e. an autocrine regulation), or by serum proteins such as immunoglobulins or complement.

Two other types of cell often present in chronic inflammatory lesions are the epithelioid cell and the multinucleated giant cell, both of which also derive from monocytes. Epithelioid cells in granulomas have characteristics that resemble those of macrophages. Multinucleated giant cells are formed by fusion of (exudate) macrophages, and not by nuclear division without cytoplasmic division. There are two types of multinucleated giant cell: the Langerhans type with relatively few nuclei arranged peripherally in the cytoplasm, and the foreign-body type with many nuclei dispersed throughout the cytoplasm.

Cell systems

Cells are usually identified primarily on the basis of their morphological characteristics, but such criteria alone are often insufficient for the identification of cells, and therefore other characteristics must be taken into account such as the presence of nonspecific esterases or other cytoplasmic enzymes, or ectoenzymes, the binding of monoclonal antibodies specific for antigens on mononuclear phagocytes, the presence of membrane receptors, or the capacity of immune phagocytosis. Since the specificity and the sensitivity of the available markers and techniques are not yet optimal, it is not possible to classify a cell as a mononuclear phagocyte with the use of only one marker. Classification of a cell population as a mononuclear phagocyte must therefore be based on a combination of properties.

Cells sharing a common morphology, origin, function or other properties may be considered collectively as forming a system. Many attempts have been

made in the past to define the system formed by phagocytic cells (Table 2). Metchnikoff was the first to use the term 'macrophages' (i.e. big eaters), because these cells are capable of ingesting large particles such as erythrocytes, spermatozoa, protozoa, etc., as opposed to the polymorphonuclear leukocytes or granulocytes, which he termed 'microphages', since these cells are only able to take up smaller particles (e.g. bacteria). Metchnikoff already recognized the close relationship between the phagocytic cells in the spleen, lymph nodes and bone marrow, and the macrophages outside these organs (e.g. in the connective tissue), which led him to introduce the term 'macrophage system' (Table 2). Kiyono introduced the term 'histiocytic cell system'. Aschoff developed this concept further and grouped several kinds of cell together in the 'reticulo-endothelial system' in which he included endothelial cells, fibrocytes, reticular cells, reticuloendothelial cells, Kupffer cells, histiocytes, splenocytes and monocytes. The concept of the reticuloendothelial system has been widely criticized (see Further reading). Maximow considered the term reticuloendothelial system inappropriate, because the vascular-endothelial cell is very different from the histiocyte and even more so from the reticular cell. Thomas criticized the term reticuloendothelial system and reintroduced the term 'reticulo-histiocyte system', which had been proposed by Volterra (Table 2).

Mononuclear phagocyte system

Since neither the concept of the reticuloendothelial system nor that of the reticulohistiocyte system provides a fully satisfactory framework into which the current knowledge of phagocytic mononuclear cells can be fitted, the concept of the mononuclear phagocyte system (MPS) was introduced in 1969. This concept is based on what is known about the morphology, function, origin and kinetics of the mononuclear phagocytes. The cells now assigned to the MPS are shown in Figure 1.

Candidate cells for the MPS

Dendritic cells and Langerhans cells are considered as candidates for the MPS because of their bone-

Figure 1 Mononuclear phagocyte system.

marrow origin, and their morphological and/or functional characteristics *Dendritic cells* occur in lymphoid organs, e.g., lymph nodes, thymus, and spleen, but also in organs such as lungs, skin, liver, small intestine, etc., originate from precursor cells in the bone marrow. These precursor cells are not yet characterized nor are the mononuclear cells in the circulation that differentiate in the tissues into dendritic cells. In cultures of bone marrow and blood mononuclear cells, in the presence of GM-CSF and IL-4, dendritic cells develop, which supports the bone-marrow origin of these cells. Stem cell factor (*e-kit* ligand) increases the yield of dendritic cells, and maturation of dendritic cell is promoted by TNF, LPS and other agents. Furthermore, glucocortico-

steroid, which induce a rapid decline of circulating mononuclear cells, including monocytes, cause also a rapid disappearance of dendritic cells from the tissues. Together, these findings support the view that dendritic cells derive from precursors in the bone marrow, but whether monocytes can differentiate in dendritic cells is still uncertain. Although dendritic cells have also many features in common with macrophages, such as cell-surface markers, functions like endocytosis, antigen processing and presentation, these cells can still not yet be considered as bona fide mononuclear phagocytes, because their derivation from monocytes has not yet been firmly established.

Langerhans cells have the same life history and functions as dendritic cells. They derive also from precursors in the bone marrow cells, and circulating mononuclear cells that migrate to the skin differentiate into Langerhans cells. The sojourn time of Langerhans cells in the skin is short and next the cells are transported, via the lymph draining the skin, as veiled cells, which are cells with long cytoplasmic viels, to the lymph nodes where they reside as interdigitating cells.

Cells not belonging to the MPS

Reticulum cells and fibroblasts, present in connective and lymphoid tissues and in various organs, and mesothelial cells of serous cavities, have morphological characteristics giving them some resemblance to macrophages, with which they are often confused. However, these cells are not regarded as mononuclear phagocytes, because they lack other characteristics of macrophages. Furthermore, these cells do not originate in the bone marrow, but renew themselves by division locally in the tissues. Confusion has been caused by adjectives applied to the reticulum cells, histiocytic reticulum cells (syn. histiocytes) and interdigitating reticulum cells are macrophages, and dendritic reticulum cells, reticular cells, and metalophil cells are all reticulum cells.

Terminology of mononuclear phagocytes under various conditions

In many reports, the mononuclear phagocytes participating in an inflammatory reaction (whether induced experimentally or occurring spontaneously) are not defined carefully, and various terms are used interchangeably. The characteristics of the mononuclear phagocytes in an inflammatory exudate depend on the inducing agent, the method of isolation, the developmental stage and the functional state of the cells. The mononuclear phagocytes in an

inflammatory exudate may be in different developmental stages, including resident macrophages already residing in the tissues or body cavity before the onset of the inflammation, monocytes recruited from the circulation that differentiate into exudate macrophages, and monocyte precursors (i.e. dividing mononuclear phagocytes derived from the bone marrow).

Since the cells in an inflammatory exudate can be quite heterogeneous, they should be characterized cautiously. To indicate the degree of heterogeneity of the population of cells in the exudate, it is essential to report not only qualitative but also quantitative data for each characteristic.

The terminology applied to the cells in an inflammatory exudate is generally unclear. For example, terms such as 'stimulated', 'activated', 'elicited' and 'induced' are used interchangeably. To deal with this problem, the following definitions can be used:

1. *Resident macrophages*. Macrophages present at any given site in the absence of exogenous or endogenous inflammatory stimulus. These cells may occur in an inflammatory exudate as a subpopulation because they were already present before the stimulus was applied. They are also called 'normal macrophages'.
2. *Exudate macrophages*. Macrophages occurring in an inflammatory exudate.
3. *Exudate-resident macrophages*. These cells are a transitional form between resident and exudate macrophages.
4. *Activated macrophages*. Macrophages with increased functional activity induced by a given stimulus *in vivo* or *in vitro*. Activation thus implies a new functional activity of a cell or an increase in one or more of these activities. Before activation, these cells may have been resident or exudate macrophages. Explicit mention should be made of how the macrophages were stimulated and how activation was measured.
5. *Elicited macrophages*. Macrophages attracted to a given site by a given substance. This term only indicates the accumulation of (exudate) macrophages at a particular site, and does not refer to the developmental stage of the cells or their functional state. An elicited population of cells is usually heterogeneous in these respects. Since 'elicited' and 'evoked' mean the same thing, use of the latter term is acceptable.

The term *stimulated macrophage* is imprecise, because stimulation means the application of a stimulus that may result in the elicitation and/or acti-

vation of cells. This adjective should not be used. The term *induced macrophage* is also inexact and should not be used, since induced can imply either elicited or activated.

Other terms used in relation to mononuclear macrophages

The terms *accumulation* and *proliferation* of cells are often used erroneously. Proliferation should be reserved for cases in which the increase in the number of cells is known to be due to division of cells already present at or recruited to a site. The term accumulation should be used for the increase of the number of cells caused by migration of (nondividing) cells from other sites.

A distinction should also be made between *differentiation* and *specialization*: the former refers to a change in the morphological development in the direction of another morphological stage, whereas the latter means a change in the functional state of a cell in a special direction.

MOTILITY OF IMMUNE CELLS

Liana Harvath, Laboratory of Cellular Hematology, Division of Hematology, Center for Biologics Evaluation and Research, Food and Drug Administration, Bethesda, Maryland, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved. Published by Elsevier Ltd.

Immune cell migration is a primary host defense mechanism for the mobilization of leukocytes to inflammatory sites and the development of cell-mediated immune responses. Initiation of migratory responses occurs when signal molecules interact with plasma membrane receptors, triggering cytoskeletal reorganization and cell shape change. Motile responses may be random, chemokinetic, chemotactic or haptotactic, and are classified by *in vitro* assays which quantify the directional responses of cells. Random migration of unstimulated motility and chemokinetic migration, i.e. stimulated random movement of cells in the absence of a stimulus gradient, are motile responses which do not have consistent directionality. In contrast, chemotactic and haptotactic responses are directional; they occur when cells are exposed to a signal gradient and the cells migrate toward an increasing concentration of the stimulus. Chemotactic responses occur when the signal is a fluid phase gradient, whereas haptotactic responses occur when the stimulus gradient is attached to a substratum. The relative importance of random, chemokinetic, chemotactic and haptotactic motility *in vivo* has not been determined. All of these motile responses may be involved in the mobilization of immune cells to inflammatory sites.

Leukocyte chemoattractants

A variety of molecules (chemoattractants) stimulate the directed migration of immune cells. Leukocyte chemoattractants may be generated at inflammatory sites or as a consequence of immune cell interactions and may serve to regulate the directed recruitment of specific leukocyte subsets to inflammatory foci *in vivo*. Some of the most potent leukocyte chemoattractants are summarized in Table 1. Neutrophils and monocytes share chemotactic responsiveness to several chemoattractants, including a cleavage product of the fifth component of complement (C5a), synthetic *N*-formyl-methionyl peptides which are structurally similar to *N*-formyl peptides generated by bacteria, arachidonic acid lipoxygenation metabolites such as leukotriene B₄ and platelet-activating factor.

Numerous secreted proteins of approximately 70–90 amino acids in length have been identified as chemokines. Some chemokines are generated constitutively; however, most chemokines act as second-

C-C chemokines	
MCP-1	Monocyte, basophil
MIP-1 α,β	Neutrophil, eosinophil, basophil, monocyte, T lymphocyte
RANTES	Monocyte, eosinophil, T lymphocyte
I-309	Monocyte
C-X-C chemokines	
IL-8/NAP-1	Neutrophil, basophil
CTAP-III/NAP-2	Neutrophil, basophil
gro/MSGA	Neutrophil
ENA-78	Neutrophil
SDF-1	Neutrophil, monocyte, T lymphocyte

ary cell activation signals during inflammatory responses. Chemokines have been divided into three groups (C, C-C and C-X-C) based on the number and arrangement of cysteines. The C chemokines have two cysteines. The C-C and C-X-C chemokines have four cysteines and are distinguished by the presence (C-X-C) or absence (C-C) of a single amino acid between the first and second cysteines. Cysteines 1 and 3 and cysteines 2 and 4 form disulfide bonds in C-C and C-X-C chemokines. The chemokines exhibit 20–30% amino acid sequence identity across groups and can be substantially more conserved within groups.

Examples of selected chemokines and their responding cell types are provided in Table 1. Only one C chemokine, lymphotactin, has been identified, whereas more than a dozen each of C-C and C-X-C chemokines have been discovered. The chemokines exhibit specificity for leukocyte types. The C-X-C chemokines predominantly attract neutrophils; however, lymphotactin and most C-C chemokines do

not. Most C-C chemokines attract monocytes, whereas lymphotactin and C-X-C chemokines do not. One C-C chemokine, MIP-1 α , β , attracts neutrophils, eosinophils, basophils, monocytes and T lymphocytes. The other C-C chemokines do not stimulate neutrophil migration. A chemokine distantly related to C-X-C and C-C chemokines, SDF-1, exhibits a broad spectrum of activity, attracting neutrophils, monocytes and T lymphocytes. SDF-1 is the most active T lymphocyte chemoattractant thus far identified and is also a potent stromal cell-derived preB cell growth-stimulating factor.

Chemoattractant receptors

Leukocyte chemoattractant receptor primary structures have been deduced from cloned cDNAs for *N*-formyl peptides, C5a, platelet-activating factor and eight of the chemokines. All of the receptors are seven-transmembrane domain rhodopsin-like G protein-coupled receptors. Their sequences are all approximately 350 amino acids in length and they share greater than 20% amino acid identity with each other. A general structural model of these receptors has been developed from a statistical analysis of sequences found in the hydrophobic domains and the known structures of rhodopsin and bacteriorhodopsin. The primary structural features include 1) an extracellular amino-terminus, 2) an intracellular carboxy-terminus, 3) seven α -helical transmembrane domains that are oriented perpendicularly to the plasma membrane, with kinks occurring in transmembrane domains II, IV, V, VI and VII by intrahelical prolines, and 4) three intracellular and three extracellular connecting loops comprised of hydrophilic amino acids. The amino-terminal segments of the receptors are usually acidic and contain potential sites for asparagine-linked glycosylation. The carboxy-termini are rich in serine and threonine residues, which may serve as phosphorylation sites for receptor desensitization, as occurs for rhodopsin and β_2 -adrenergic receptors.

Structural changes in chemoattractant-stimulated leukocytes

Within seconds after adherent leukocytes are exposed to a chemoattractant, plasma membrane ruffling occurs and the cells elongate with a broad lamellipodium formed anteriorly and a thin uropod formed posteriorly. Cytoplasmic actin filaments are assembled (polymerized) near the plasma membrane and appear in increased concentrations in the lamellipodium and uropod, whereas intermediate filaments are found in the core of the uropod and microtubules

are concentrated in the body of the cell extending toward, but not into, both poles of the oriented leukocyte. The kinetics of actin polymerization and depolymerization correlate closely with leukocyte shape change and are believed to be crucial events in chemotaxis. During leukocyte polarization, chemoattractant receptors are concentrated near the lamellipodium, whereas coated pits, clathrin-containing structures that mediate pinocytic uptake, are clustered at the uropod. Chemoattractant ligand is internalized under physiologic temperature conditions of 37°C and the ligand has been found to transiently associate with cytoskeletal proteins in neutrophils. Adherent, chemoattractant-stimulated neutrophils also exocytose specific (secondary) granules which contain an intracellular pool of *N*-formyl peptide chemoattractant binding sites. It has been proposed that chemoattractant receptor replenishment occurs at the lamellipodia of migrating neutrophils by either the recycling of previously internalized receptors or by the translocation of a receptor pool associated with neutrophil-specific granules or other organelles which are released during chemotaxis. Neutrophil receptors appear to move in a consistent pattern from the lamellipodium toward the uropod as the neutrophils exhibit amoeboid-like migration in a relatively straight line up the concentration gradient. Neutrophil and monocyte exposure to relatively high concentrations of chemoattractants also activates the extrusion of lysosomal enzyme-containing granules (degranulation) and increased oxygen consumption resulting in oxygen radical generation. Although degranulation and oxygen radical production do not appear to be involved in the initiation of chemotaxis, these events may modulate the chemotactic response and enhance the microbicidal activity of phagocytic leukocytes mobilized to critical sites *in vivo*. The dramatic alterations in leukocyte plasma membranes as well as the rapid changes in cytoskeletal architecture which accompany leukocyte exocytosis, pinocytosis and polarization all appear to be essential morphologic rearrangements that occur during chemotaxis. The precise sequence of structural and biochemical changes required for leukocyte chemotaxis remain undefined.

Biochemical changes in chemoattractant-stimulated leukocytes

Transient elevations in intracellular Ca²⁺, Na²⁺ and cyclic AMP levels, as well as membrane potential changes, occur within seconds after leukocyte exposure to chemoattractants. Chemoattractant binding to receptor activates phospholipase C via guanine nucleotide binding-proteins (G proteins).

The G_{i2} and G_{i3} proteins have been found to be the primary G proteins associated with chemoattractant receptors. Upon activation by chemoattractant binding to the receptor, the Gi dissociates into the GTP-bound $G\alpha$ subunit and $\beta\gamma$ subunit complex. The $G\beta\gamma$ complex regulates phospholipase C β isoforms in leukocytes. Phospholipase C β activation results in the breakdown of phosphatidylinositol 4,5-bisphosphate to form inositol 1,4,5-triphosphate (IP3) and 1,2 *sn*-diacylglycerol (DAG). The two products of this reaction, IP3 and DAG, activate calcium mobilization (via IP3) and protein kinase C (via DAG). Calcium and protein kinase C appear to be involved in leukocyte cytoskeletal protein modifications. Intracellular free Ca^{2+} is increased in the lamellipodia of migrating neutrophils and affects actin polymerization in chemoattractant-stimulated neutrophils. Other cytoskeletal protein reorganizations may occur via DAG which stimulates protein kinase C to phosphorylate cytoskeletal proteins. Inhibitors of protein kinase C, kinase A and tyrosine kinases inhibit neutrophil chemotaxis to several chemoattractants. These findings and others demonstrating the phosphorylation of cytoskeletal proteins in chemoattractant-stimulated neutrophils suggest that cytoskeletal protein phosphorylation is involved in neutrophil chemotaxis.

The coupling and uncoupling of G protein with a chemoattractant receptor may occur via modifications to the G protein and/or the receptor protein. Protein carboxyl methylation may be involved in the modifications of these proteins. Several macrophage membrane proteins are carboxyl methylated by S-adenosylmethionine in an enzymatic reaction that is greatly stimulated by the presence of guanine nucleotides. Macrophage chemotaxis is suppressed by bacterial toxin inhibitors of G proteins and by methylation inhibitors, strongly suggesting that carboxyl methylations may regulate the function of some membrane G proteins.

The receptors for several different chemoattractants have been reported to exist in two affinity states and guanine nucleotides regulate the receptor affinity. One model, which assumes a static population of high- and low-affinity receptors, has proposed that the high-affinity receptors transduce chemotaxis, while the low-affinity receptors transduce oxygen radical production. A second model, which takes into account interconverting receptor states rather than static populations of receptors, postulates that all chemoattractant receptors may participate in all leukocyte responses coupled via G proteins; the responses with low 50% effective doses (ED_{50} s) require only a few occupied receptors, whereas the

responses with high ED_{50} s require many receptors to initiate and sustain the response.

Chemoattractant binding to neutrophils and monocytes activates phospholipase A_2 and results in arachidonic acid release. Free arachidonic acid is converted by cyclo-oxygenase to thromboxanes and prostaglandins and by lipoxygenation to a variety of hydroxyeicosatetraenoic acids, including leukotrienes. Peak intracellular concentrations of these metabolites occur within minutes after chemoattractant stimulation. The precise roles of these products are unknown; however, they may regulate leukocyte responsiveness to chemoattractants and participate in alterations of leukocyte plasma membranes during activation.

Migratory properties of immune cells

Lymphocytes differ from neutrophils and monocytes in their *in vitro* and *in vivo* migratory properties. Neutrophils are the most rapidly motile immune cells and are generally the first leukocytes to appear at an inflammatory site. Monocytes usually appear after neutrophils and precede lymphocytes at an inflammatory locus.

The emigration of neutrophils and monocytes from the vasculature appears to be regulated by three distinct molecular signals, which include interactions between selectin-carbohydrate, chemoattractant-receptor and integrin-immunoglobulin family interactions which occur in sequence. Selectins mediate the initial tethering of neutrophils and monocytes to the endothelial cells and their rolling on the vessel wall. Chemoattractant-receptor interaction, which stimulates the events reviewed in the preceding sections, also alters the number of integrin molecules expressed on neutrophil and monocyte surfaces and provokes conformational changes in integrins which modulate the adhesiveness of these leukocytes to their endothelial substrata. The endothelial cells express immunoglobulin superfamily molecule members which serve as integrin ligands for leukocytes. This complex series of events is coordinated such that these cells may attach, migrate and detach from endothelial substrata in response to inflammatory stimuli.

Lymphocyte recirculation involves distinct traffic patterns for naive and memory lymphocytes. Separate streams appear to exist for lymphocytes that recirculate through the skin, gut and lung and drain into their associated lymphoid tissues. Naive and memory lymphocytes prefer different recirculation pathways. Upon exposure to antigen, naive lymphocytes with receptors specific for the antigen are stimulated to clonally expand and are converted to

memory lymphocytes that have altered expression of adhesion receptors and circulatory patterns. For peripheral tissues and lymph nodes, memory lymphocytes emigrate preferentially through tissue endothelium, whereas naive lymphocytes enter the lymph node through high endothelial venules (HEVs). The emigration of lymphocytes through peripheral node HEVs appears to require sequential signals that are analogous to those required for neutrophil and monocyte emigration from the vasculature. The putative lymphocyte chemoattractant secreted by peripheral lymph node HEVs and the chemoattractant receptor that is selectively expressed on naive lymphocytes that recirculate through peripheral lymph node HEVs remain to be determined.

MOUSE INBRED STRAINS

Moyha Lennon-Pierce and Janan T Eppig, The Jackson Laboratory, Bar Harbor, Maine, USA

In mouse and human, the susceptibility and resistance to diseases, as well as the response to therapeutic agents, involves a complex interplay between multiple genetic and environmental factors. Here we focus on a few well-studied inbred strains of mice that display particular immunological characteristics. Response to infectious agents, including tumor-causing viruses and some of the opportunistic infections found in patients with the acquired immune deficiency syndrome (AIDS) are included in this brief review.

As the Human Genome Mapping Project has progressed, many genetic diseases with single gene etiologies have been mapped. However, much remains to be learned. Diseases defined by single gene mutations can show a wide spectrum of phenotypes influenced by modifier genes, genetic background and environment. Other diseases, such as cancers and diabetes, are polygenic and the genetic contributions to these diseases are not yet understood.

As a major model organism with extensive genetic tools, the mouse is providing important insights into human genetic diseases. The Mouse Genome Data-

base (MGD) developed at the Jackson Laboratory, is a critical link to providing researchers with mouse genetic and phenotypic data and cross-connecting these data with analogous information on human genes and phenotypes. MGD contains information on genetic markers, mammalian homology (>50 species), probes, polymerase chain reaction (PCR) primers, haplotype data from backcross mapping panels, gene expression data, strain distribution patterns from recombinant inbred and recombinant congenic strains, quantitative trait loci (QTL), MIT DNA marker maps, Chromosome Committee reports and phenotypic information in the Mouse Locus Catalog (MLC) and Dr MFW Festing's inbred strain listing. There are links with other genomic databases including the human Genome Database (GDB) and Mendelian Inheritance in Man (OMIM), as well as DNA sequence databases – GenBank, GSDB, EMBL, DDBJ.

Inclusion of inbred strain information collected over many years at the Jackson Laboratory is in MGD future plans. This will enable an investigator to search for data on the anatomy, biochemistry, morphology, physiology, disease susceptibility or resistance and response to therapeutic reagents, etc. of inbred strains of mice. Our World Wide Web URL is: <http://www.informatics.jax.org/mgd.html> and help is available through e-mail at mgi-help@informatics.jax.org.

A/J

Origin

Cross between a Cold Spring Harbor albino and a Bagg albino (Strong, 1936). Carries a Y chromosome of Asian *Mus musculus musculus* origin (Tucker *et al*, 1992).

Predominant characteristics

1. A four locus model (*Pas1*, -2, -3, -4) of pulmonary adenoma susceptibility (Malkinson *et al*, 1985).
2. Cranio-facial disorders (Juriloff *et al*, 1995).
3. Hyperreactive airway response to a variety of bronchoconstricting agents including acetylcholine (Ewart *et al*, 1995), 5-hydroxytryptamine (Levitt *et al*, 1989) and ozone (Takahashi *et al*, 1995). *Bhr1*, -2, -3, -4 bronchial hyperresponsiveness genes mapped by QTL analysis (De Sanctis *et al*, 1995).
4. Extreme sensitivity to carcinogens (Stoner *et al*, 1993).

Infectious agents

Susceptible to: Friend leukemia virus, herpesvirus type 1, Moloney virus, *Candida albicans*, *Giardia muris*, *Leishmania tropica*, *Schistosoma mansoni*, *Taenia taeniformis*, *Trypanosoma brucei*, *T. congolense*, *T. cruzi*, *T. musculi*, *T. rhodesiense*, *T. vivax*, *Corynebacterium kitchneri*, *Pseudomonas aeruginosa*, *Rickettsia tsutsugamushi*, *Ectromelia* (Nesbitt *et al*, 1984), *Plasmodium chabaudi* (Stevenson *et al*, 1992), *P. berghei* (Contreras *et al*, 1980), *Cryptococcus neoformans* (Rhodes *et al*, 1980).

Resistant to: mouse hepatitis virus 3; *Brugia malayi*, *Echinococcus multilocularis*, *Encephalitozoon cuniculi*, *Entamoeba histolytica*, *Fasciola hepatica*, *Trichomonas vaginalis*, *Nematospores dubius* reinfection, *Listeria monocytogenes*, *Mycobacterium bovis* BCG, *M. lepraemurium*, *M. tuberculosis*, *Salmonella typhimurium*, *Schistosoma japonicum*, *Eimeria ferrisi*, *Histoplasma capsulatum* (Nesbitt *et al*, 1984).

Immunological parameters

Deficient in: natural killer (NK) cell activity (Pollack *et al*, 1982), tumor necrosis factor alpha (TNF α) (Gosselin *et al*, 1995), hemolytic complement (Rhodes *et al*, 1980) and interferon gamma production (Lucchiari *et al*, 1992). Limited immunoglobulin G (IgG) response, sufficient IgM response (Miller *et al*, 1992). Resists amyloid formation (Nesbitt *et al*, 1984).

AKR/J

Origin

Somewhat obscure early history. Bred as a high leukemia strain (Furth, 1946). There are striking differences between AKR substrains, particularly AKR/J and AKR/Cum (Acton *et al*, 1973). AKR/J carries a *Mus musculus domesticus* origin of Y chromosome (Tucker *et al*, 1992).

Predominant characteristics

1. High leukemia and high viremia (DiFronzo *et al*, 1993).
2. An 80–90% susceptibility to spontaneous T cell lymphomagenesis (Yamada *et al*, 1994; Haran-Ghera *et al*, 1995a; Michie *et al*, 1995) and a 5–10% susceptibility to spontaneous B cell lymphomagenesis (Haran-Ghera *et al*, 1995b).

Infectious agents

Susceptible to: lactate dehydrogenase-elevating virus-induced poliomyelitis (Anderson *et al*, 1995), MCF-247 recombinant virus (Peled *et al*, 1995), 3 Gross leukemia virus (Rich *et al*, 1995), murine herpes virus (Kapoor *et al*, 1992), Friend virus (Silver, 1986), *Ectromelia* (Wallace *et al*, 1985), *Trichuris muris* (Else *et al*, 1992), *Echinococcus multilocularis* (Gottstein *et al*, 1994), and *Neisseria meningitidis* infection (Woods *et al*, 1988). Resistant to: *Trichinella spiralis* infection (intermediate) (Kennedy *et al*, 1991). Low dental caries after infection with JC-2 *Streptococcus mutans* (Kurihara *et al*, 1991).

Immunological parameters

Spontaneous lymphocytic choriomeningitis (LCM) (Allan *et al*, 1989). High tumorigenesis with MNU (Angel *et al*, 1993) and ENU (Diwan *et al*, 1973). Low immunosuppression by ultraviolet B radiation (Noonan *et al*, 1994). Resistant to DMH-induced colon carcinogenesis (Rosenberg *et al*, 1995). Low susceptibility to the induction of autoimmune orchitis (Tokunga *et al*, 1993).

BALB/c

Origin

Halsey J Bagg albino to LC Strong in 1920 (Strong, 1978). Differences in BALB/c substrains have been documented (Potter, 1985, Hilgers *et al*, 1985). Carries an Asian *Mus musculus musculus* Y chromosome (Tucker *et al*, 1992).

Predominant characteristics

1. Pre-neoplastic plasmacytomas easily induced using pristane (Potter *et al*, 1964) or silicone gels (Potter *et al*, 1994).

Infectious agents

Susceptible to: Theiler's murine encephalomyelitis virus (TMEV) (BALB/cAnNCr), mouse hepatitis virus (Godfraind *et al*, 1995) with BALB/cBy showing resistance (Nicholson *et al*, 1996), *Leishmania major* (Noben-Trauth *et al*, 1996), *Trypanosoma congolense* (Ogunremi *et al*, 1995), chronic Chagas'

cardiomyopathy in postacute *Trypanosoma cruzi* infection (Rowland *et al*, 1992), *Hymenolepis nana* (Asano *et al*, 1993), *Salmonella typhimurium* (Xu *et al*, 1995).

Resistant to: *Eimeria vermiformis* (Rose *et al*, 1996), *Helicobacter* infections (Mohammadi *et al*, 1996), *Plasmodium berghei* ANKA (Moumaris *et al*, 1995), *Candida albicans* (Costantino *et al*, 1995).

Immunological parameters

Susceptible to colon tumors (Moen *et al*, 1996). High IgE responder (Mori *et al*, 1990). Low or non-responder to tumor induction by SV40 large T Ag (Zerrahn *et al*, 1996).

C3H

Origin

LC Strong originated C3H strain in 1920 from a cross of a female Bagg albino × DBA male with selection for high mammary tumor incidence (Strong, 1935). Significant differences among substrains. Carries a Y chromosome of *Mus musculus domesticus* origin (Tucker *et al*, 1992).

Predominant characteristics

1. The C3H/HeJ-*Ips*^d substrain carries a defective lipopolysaccharide response allele while most of the other C3H substrains carry the *Ips*⁺ allele for normal LPS response (Glode *et al*, 1976; Ding *et al*, 1995).
2. High incidence of spontaneous and induced mammary tumors (Outzen *et al*, 1985; Lukacher AE *et al*, 1995), although in some C3H substrains this characteristic may be reduced or lost in time (TJL Technical Support, 1996). MMTV characterized by Lee and Eicher (1990).

Infectious agents

Susceptible to: MuLV (Nouvel *et al*, 1993), lymphocytic choriomeningitis (LCM) virus (Stellrecht *et al*, 1992), encephalomyocarditis virus-induced myocarditis (Okada *et al*, 1992), measles virus (Finke *et al*, 1995), Junin virus (Scolaro *et al*, 1991), cardiovirulent coxsackievirus B3 (CVB3) (Tracy *et al*, 1992); *Mycobacterium tuberculosis* (Lecoeur *et al*, 1989), L-form *Salmonella typhimurium* (C3H/HeJ) (Nishikawa *et al*, 1994), Lyme borreliosis (*Borrelia burgdorferi*) (Fikrig *et al*, 1992), *Trypanosoma musculi* (Wechsler *et al*, 1988), *Cryptosporidium parvum* (Enriquez *et al*, 1991), *Candida albicans*, *Mycobacterium bovis* BCG and *Schistosoma mansoni* (Jeevan *et al*, 1992), leishmaniasis (Laskay *et al*, 1995), (*Treponema hyodysenteriae* Serpulina (Mysore *et al*, 1992).

Resistant to: mouse hepatitis virus (Decimo *et al*, 1993), Murray Valley encephalitis virus (Sangster *et al*, 1993); *Cryptococcus neoformans* (Rhodes *et al*, 1980), *Trypanosoma cruzi* (Tarleton, 1990).

Immunological parameters

Resistant radiation-induced pulmonary tumors (Johnston *et al*, 1995). Hyporeactive airway response to ozone, and resistant to silicosis (Ohtsuka *et al*, 1995). Females poor Hya (H-Y) antigen responders to syngeneic male skin grafts (Desquenue-Clark *et al*, 1992). High IgE responder (Mori *et al*, 1990). Females susceptible to cardiac calcinosis (Brunnert *et al*, 1990). Susceptible to experimental autoimmune

orchitis (Tokunaga *et al*, 1993) and spontaneous and induced liver tumors (Rumsby *et al*, 1994). Low responder to cholera toxin (Elson, 1992).

C57BL/6J

Origin

CC Little, JAX, developed this strain in 1921 from a mating of female 57 with male 52 from Abbie Lathrop's stock. Substrains C57BL/6 and C57BL/10 were separated prior to 1937 (Russell, 1978). LINE-1 elements from *Mus spretus* detected in the C57BL/6J background suggest a maximum of 6.5% of the C57BL/6J genome may be *Mus spretus* derived (Rikke *et al*, 1995). Carries an Asian *Mus musculus musculus* Y chromosome (Tucker *et al*, 1992).

Predominant characteristics

1. Develops mouse acquired immune deficiency syndrome (MAIDS) after infection with LP-BM5 MuLV (Simard *et al*, 1994; Huang *et al*, 1995).
2. Extremely high preference for drugs of abuse, including alcohol (Chadha *et al*, 1991); Phillips *et al*, 1994), morphine (Berrettini *et al*, 1994; Belknap *et al*, 1995) and cocaine (Lopez *et al*, 1992; Watzl *et al*, 1992; Grahame *et al*, 1995).
3. Multi-locus model (*Ath-*) for atherosclerotic lesions induced by an atherogenic diet (Nishina *et al*, 1993).
4. Alopecia areata-like hair loss (Thornburg *et al*, 1973; Militzer *et al*, 1986).

Infectious agents

Contrast with the A strain listing in a review by Nesbitt and Skamene (1984). Susceptible to: rabies virus (Lodmell, 1982); induction of amyloidosis (Hebert *et al*, 1990), *Toxoplasma gondii* (McLeod *et al*, 1984), *Mycobacterium avium* (Hubbard *et al*, 1992). Resistant to MTV (Murray *et al*, 1967), polyoma virus-induced tumorigenesis (Freund *et al*, 1992), experimental encephalomyocarditis (Mendel *et al*, 1995), *Plasmodium chabaudi* (Yap *et al*, 1992), *Mycoplasma fermentans* (Gabridge *et al*, 1972), *Angiostrongylus costaricensis* (Ishii *et al*, 1989), *Histoplasma capsulatum* (Wu-Hsieh, 1989), *Lyme borreliosis*-induced carditis (Barthold *et al*, 1990), *Trypanosoma cruzi* (Reed *et al*, 1994), *Actinomyces viscosus*-induced bone loss (Gilbert *et al*, 1988), mousepox-1 (Brownstein *et al*, 1992).

Immunological parameters

Resist arthritis induction (Yong *et al*, 1988) and ovalbumin-induced anaphylactic shock (Cowdery *et al*

al, 1982). High responder to dextran (Fernandez, 1992). Intermediate IgE responder (Mori *et al*, 1990). Endotoxin-responsive (*Lps*ⁿ) to TCDD (Clark *et al*, 1994). High responder to cholera toxin (Elson, 1992).

C57BL/10

Origin

Developed at JAX from a mating of a female 57 × male 52 from Abbie Lathrop (Russell, 1978). Carries the Asian *Mus musculus musculus* Y chromosome (Tucker *et al*, 1992).

Predominant characteristics

1. Predominant substrain used as the genetic background for the production of many histocompatibility congenic resistant lines (Snell *et al*, 1965).

C57BLKS/J (previously C57BL/KsJ)

Origin

Derived from nonpedigreed mice bred at JAX and widely distributed. Returned to JAX after the 1947 Bar Harbor fire. Genomic analysis of the C57BLKS inbred strain shows that 84% of the alleles in this strain are shared with C57BL/6 and 16% are shared with DBA/2J indicating genetic contamination early in the strain's history (Naggert *et al*, 1995; Slingsby *et al*, 1995). The diabetes mutation, *Lepr*^{db} arose on this strain and the effects of the gene are particularly severe on this background (Hummel *et al*, 1966; Leiter, 1987). Carries an Asian *Mus musculus musculus* Y chromosome (Tucker *et al*, 1992).

CBA/J**Origin**

Bred for low mammary tumor incidence from a cross of a Bagg albino female and a DBA male (Strong, 1936). Genetic contamination is thought to account for the differences between substrains. Carries a *Mus musculus domesticus* origin Y chromosome (Tucker *et al*, 1992).

Infectious agents

Susceptible to: Theiler's virus (Rodriguez *et al*, 1990), measles virus (Neighbour *et al*, 1978), *Ectromelia* virus strain C (Ermolaeva *et al*, 1972), *Bacillus piliformis* (Tyzzer's disease) (Waggie *et al*, 1981), *Onchocerca lienalis microfilariae* (Folkard *et al*, 1995), *Mycobacterium lepraemurium* (Roch *et al*, 1991), *Schistosomia mansoni* (Henderson *et al*, 1993).

Resistant to: murine herpesvirus (Kapoor *et al*, 1992), rabies virus (Lodmell *et al*, 1995); *Salmonella typhimurium* strain (Matsiota-Bernard *et al*, 1993), *Neisseria gonorrhoeae* (Johnson *et al*, 1989), *Plasmodium berghei* ANKA strain (Contreras *et al*, 1980), *Streptococcus mutans*-induced dental caries (Kurihara *et al*, 1991).

Immunological parameters

High gross tumor incidence (Storer, 1966; Smith *et al*, 1973). Susceptible to ozone toxicity (Goldstein *et al*, 1973) and streptozoin-induced renal epithelial tumors (Hard, 1985).

DBA/1**Origin**

Developed in 1909 by CC Little, while in Castle's laboratory at Harvard University. Carries a Y chromosome of *Mus musculus domesticus* origin (Tucker *et al*, 1992). DBA/1 and DBA/2 have identical endogenous viral genotypes (Atchley *et al*, 1991).

Predominant characteristics

1. Spontaneous inflammatory and erosive joint disease (Nordling *et al*, 1992), and collagen-induced arthritis (Hansson *et al*, 1993).

Infectious agents

Susceptible to: *Mycoplasma fermentans* (Gabridge *et al*, 1972), *Trypanosoma cruzi* (Rowland *et al*, 1992), *Coxiella burnetii* infection (Scott *et al*, 1978), *Ectromelia* (Briody, 1966). Resistant to: *Plasmodium berghei* infection (Most *et al*, 1966).

Immunological parameters

Age-dependent contact photosensitivity (Brown *et al*, 1989), low gross tumor incidence in males (Storer, 1967), DBA/1 complement sufficient, DBA/2 complement deficient (Nilsson *et al*, 1966). DBA/1 carries the H2^u haplotype, DBA/2 the H2^d haplotype (Klein *et al*, 1983). DBA/1 is resistant to most DBA/2 tumors, with nonfostered substrains carrying the mammary tumor virus (Hoag, 1963). Resistant to pristane-induced plasmacytoma development (Potter *et al*, 1992; Muller *et al*, 1996).

DBA/2

Origin

This dilute brown strain was developed by CC Little, while in Castle's laboratory at Harvard University. There are a large number of differences between the DBA/1 and DBA/2 strains. Carries a Y chromosome of *Mus musculus domesticus* origin (Tucker *et al*, 1992).

Predominant characteristics

1. Extreme aversion to drugs of abuse, including alcohol (Phillips *et al*, 1994), morphine (Berrettini *et al*, 1994), and cocaine (Tolliver *et al*, 1995).
2. Highly susceptible to audiogenic and chemically induced seizures (Desarro *et al*, 1995; Ferraro *et al*, 1995).

Infectious agents

Susceptible to: Friend virus (Bartman *et al*, 1994); *Trypanosoma cruzi* (Reed *et al*, 1994), *Candida albicans* (Ashman *et al*, 1993).

Resistant to: *Yersinia enterocolitica*-induced arthritis (Yong *et al*, 1988), allergic encephalomyelitis (Takeda *et al*, 1993), *Salmonella typhimurium* (Kita *et al*, 1992), *Mycobacterium tuberculosis* (Flory *et al*, 1992), females resistant, males susceptible to *Leishmania mexicana* (Alexander 1988), *Plasmodium chabaudi* (Stevenson *et al*, 1982).

Immunological parameters

Hemolytic complement sufficient (Rhodes *et al*, 1980). High IgE responder (Mori *et al*, 1990). DBA/2 carries the H2^d haplotype, DBA/1 carries H2^a (Klein *et al*, 1983).

SJL

Origin

Originated from Swiss Webster stock of three sources brought to JAX between 1938 and 1943. Pen-bred until 1955 when inbreeding was started by Jim Lambert (SJL = Swiss Jim Lambert). Carries a *Mus musculus domesticus* Y chromosome (Tucker *et al*, 1992).

Predominant characteristics

1. Develop spontaneous T cell proliferation-driven class II B cell lymphomas resembling the large cell lymphoma found in the human (Stavnezer *et al*, 1989; Tsiagbe *et al*, 1993).
2. High gross tumor incidence (Storer, 1966), with pre-B-cell lymphoma being the predominant tumor type (Mucenski *et al*, 1988).
3. Low IgE responder (Mori *et al*, 1990).
4. Mouse model for encephalomyelitis and encephalomyocarditis (Lindsley *et al*, 1991; Kang *et al*, 1993; Tuohy *et al*, 1995).

Infectious agents

Susceptible to: Friend virus-induced and DMBA-

induced leukemia (Dietz *et al*, 1972; Crispens, 1973); *Mesocostoides corti* (Lammas *et al*, 1990).

Resistant to: measles virus (Rammohan *et al*, 1980), P3193 and P2184 Sendai virus (Parker *et al*, 1978), street rabies virus (Perry *et al*, 1991), herpes simplex encephalitis (HSE) (Hudson *et al*, 1991); *Borrelia burgdorferi*-induced carditis (Barthold *et al*, 1990), *Cryptosporidium parvum* infection (Enriquez *et al*, 1991), B3502 *Cryptococcus neoformans* (Rhodes *et al*, 1980), fungal toxin sporidesmin-induced biliary tract injury (Bhathal *et al*, 1990).

Immunological parameters

Low NK activity (Lin *et al*, 1992). Susceptible to mercury-induced systemic autoimmunity (Kouri *et al*, 1973). Low susceptibility to ultraviolet B-induced contact hypersensitivity (Noonan *et al*, 1994). High level of catalytic antibodies after immunization with a *p*-nitrobenzyl phosphonate hapten (Tawfik *et al*, 1995) and high incidence of spontaneous amyloidosis (Taylor *et al*, 1984).

SWR/J

Origin

'Swiss' mice from Lausanne, inbred at the Rockefeller Institute from about 1926 (Lynch, 1969). Now widely used in research as a general-purpose strain. Carries a *Mus musculus domesticus*-origin Y chromosome (Tucker *et al*, 1992).

Predominant characteristics

1. High level of cholelithiasis (gallstones) (Khanuja *et al*, 1995).
2. Carries no detectable endogenous ectropic MuLV DNA sequences (Jenkins *et al*, 1982).
3. Resistant to diet-induced obesity (West *et al*, 1994).
4. Susceptible to spontaneous and induced ovarian granulosa cell tumors (Beamer *et al*, 1985, 1993) and susceptible to DMH-induced colon carcinogenesis (Rosenberg *et al*, 1995).

Immunological parameters

Hemolytic complement-deficient (Rhodes *et al*, 1980). Pertussis HSF responsive (Wardlaw, 1970).

The genus *mus* is composed of a dozen different species spread practically over the whole world with the exception of cold and arid areas, and its taxonomy has remained a matter of controversy for many decades. Modern systematics, owing much to molecular techniques, has, however, successfully characterized otherwise morphologically quite similar taxa and yielded a now reliable classification. Besides ancient and widespread classical laboratory strains, most of these taxa are now established as laboratory colonies or even inbred strains and are available to investigators.

The complex species *Mus musculus*

The polytypic species *Mus musculus* finds its origins in Asia, like many murid rodents. It can be resolved into several subspecies as described below:

Peripheral species

Mus musculus domesticus (Rutti, 1772) Mice of this species are found in western Europe, around the Mediterranean basin, in Africa, in Arabia and in the Middle East. This subspecies includes geographical races sometimes improperly designated with other Latin trinomens, such as *Mus m. brevisrostris*, *Mus m. poschiavinus*, *Mus m. praetextus* etc., but these races are biochemically and genetically identical with *Mus m. domesticus*.

Although most of the animals belonging to *Mus m. domesticus* exhibit a karyotype with 40 acrocentric chromosomes, several subpopulations have been reported with varying numbers of Robertsonian translocations in different combinations.

Mus musculus musculus (Linnaeus, 1758) Individuals of this species occupy the region from eastern Europe to Japan across Russia and northern China. Like the former subspecies, individuals of this group are either commensal or wild whereas other groups are almost exclusively wild.

Mus musculus castaneus (Waterhouse, 1843) This species is found from Sri Lanka to South-East Asia including the Indo-Malayan archipelago.

The central populations

Mus musculus bactrianus (Blyth, 1846) is found

from Iran to Pakistan. This trinomen has long been attributed to populations ranging from Iran to Pakistan. According to recent work by Din and colleagues, this is a rather heterogeneous ensemble, and the *bactrianus* species *sensu stricto* are probably limited to the Afghan valleys. An accurate taxonomical description of these central populations is still needed.

Origins of the species

None of the above-mentioned subspecies are completely genetically isolated from the other three and, in those locations where they meet, there is evidence of exchanges ranging from limited introgression to complete blending. Studying the genetic relationships between the above-mentioned subspecies, Din and colleagues have proposed that the northern part of the Indian subcontinent was the cradle of the species *Mus musculus*. According to the pattern of genetic divergence observed, they proposed that the extant peripheral subspecies resulted from a radiation proceeding from the central populations in several directions outwards (Figure 1). This would have taken place between 0.5 and 1 million years ago, according to the analysis of mitochondrial DNA by Boursot and coworkers, and would account for most of the genetic variability presently available in the species.

These taxa would have secondarily and much more recently colonized the rest of the world because

Figure 1 Map showing the proposed radiation of subspecies from a central population of *Mus musculus*.

of their capacity to interact with humans (commensalism). These exchanges justify the use of subspecific names (Latin trinomens) for their designation. The best documented cases of such gene exchanges are those occurring between *Mus m. musculus* and *Mus m. domesticus* in Europe, and between *Mus m. musculus* and *Mus m. castaneus* in Japan. In this archipelago, the two subspecies have hybridized extensively, giving rise to a unique population often referred to as *Mus m. molossinus*.

For a more exhaustive review of the genetical and ecological interactions between the various species, see Boursot *et al* (1993) and Sage *et al* (1993).

Other species of the genus *Mus sensu stricto*

Other species of the genus *Mus* are found in western Europe and in Asia.

European species

The European species are the following:

- The western Mediterranean short-tailed mouse *Mus spretus* (Lataste, 1883), found in the south of France, in Spain, Portugal and in North Africa.
- The mound-builder mouse *Mus spicilegus* (Petenyi, 1882) found in central Europe and also called *Mus hortulanus* or *Mus 4b* in previous reviews.
- The eastern Mediterranean short-tailed mouse *Mus macedonicus* (Petrov and Ruzic, 1983), also known as *Mus abbotti*, *Mus spretoideus* or *Mus 4a* and found from the former Yugoslavia to Israel and Iran. Biochemical criteria discriminate easily between these different species which, although they occur sympatrically with representatives of the complex species *Mus musculus*, never produce hybrids with them in nature. For a discussion concerning the nomenclature and systematics of these species see Auffray *et al* (1990).

Asian species

The main Asian species are the following:

- *Mus caroli*
- *Mus cervicolor*
- *Mus cookii*.

Finally, the most distantly related forms still belonging to the genus *Mus sensu stricto* (with a 40 acrocentric chromosomes complement) are the Indian pigmy species *Mus booduga* and *Mus dunni* also called *Mus terricolor*, see Sharma (1996) for details on this group.

Figure 2 represents a synthetic phylogeny of the taxa described here based on an analysis of molecular markers by She and colleagues. The multifurcations presented are points where alternative branching orders are possible due to the proximity of the splitting events and the limited resolving power of the technique. The species set described here corresponds to the group of species falling within the genus *Mus*, *sensu stricto*, which is sometimes also considered as a subgenus relatively to other more distantly related groups *Nannomys*, *Coelomys* and *Pyromys*.

Wild mice in the laboratory

Over the last 10 years, a variety of strains derived from ancestors trapped in known geographical locations and having well-defined taxonomical origins have been created in various laboratories. A list of those that are completely inbred or nearly so is given in Lyon *et al* (1996). Moreover many useful random bred stocks of wild mice are maintained in various laboratories, and a complete description of these stocks has been given in Potter *et al* (1986).

Mus m. domesticus is by far the most widely represented taxon amongst these stocks, followed by *Mus m. musculus*, *M. m. molossinus* and *M. m. castaneus*. Beside these strains, belonging to the *Mus musculus* species complex, representatives of *Mus macedonicus*, *Mus spicilegus*, *Mus spretus* and even *Mus caroli* are now maintained in the laboratory and some of them have already undergone 20 generations of sib matings.

Viable F1 offspring have been obtained between laboratory female mice and each of the European species by natural fertilization. Using artificial insemination West and colleagues recovered embryos sired by male *Mus dunni* and *Mus caroli* sperm, but

Figure 2 Phylogenetic relationships between the different species of the *Mus* genus.

failed to recover any when *Mus cervicolor* sperm was used.

Concerning interspecific hybrids, special mention must be made of *Mus spretus* because of the very large number of allelic differences involved when intercrosses are set up with any of the standard laboratory strains. Whatever the cloned DNA probe used, experience shows that it is relatively easy to find suitable restriction fragment length polymorphism (RFLPs) segregating between *Mus spretus* and laboratory strains such as C57BL/6 or BALB/c so that checking the progeny of an interspecific backcross makes gene mapping not only easier but sometimes the only way. The technique used for the first time by Robert and coworkers has been summarized in Guénet (1986). Similar crosses could be done with either *Mus macedonicus* or *Mus spicilegus*. However, they show a lesser degree of divergence from *Mus musculus* than *Mus spretus*.

The relationships between laboratory mice and wild species

Started at the beginning of this century, the establishment of genetically standardized laboratory strains owes much to the existence of a pet mouse tradition. The known pedigrees of the classical inbred strains show that many intercrosses occurred in the early part of their development, together with introductions of unknown parentage, either by purchase from pet dealers or by trapping wild animals. These laboratory lines were classically taken as being archetypes of *Mus m. domesticus* and their closeness has been demonstrated for instance by the fact that almost all of them possess the same *Mus m. domesticus* type of mtDNA. Further studies on the characterization of the Y chromosome and other genetic markers, however, have shown unambiguously that the bulk of classical inbred strains are in fact a mosaic of various genetic components derived from more than one taxon of the complex species *Mus musculus*. In particular, they almost all show a *Mus m. musculus* component (the Y chromosome in particular) that could be of Asian origin and linked to the early introduction of Japanese fancy mice (waltzing mice for instance) into the European pedigrees. Irrespective of their origin, however, it is clear that the allelic diversity they show cannot be interpreted as resulting from high mutation rates during their hundred year history. In a sense, today's classical inbred laboratory strains may be considered as interspecific recombinant inbred strains between *Mus m. domesticus* and (at least) *Mus m. musculus* and for this reason it would be wise to refer to them simply as *Mus musculus* or even *Mus 'laboratorius'*.

The approximate divergence time of *Mus musculus* from the other European species is probably around 1–2 million years as estimated by scnDNA hybridization data and it is up to 2–3 million years for the divergence between the Asian group *caroli/cooki/cervicolor* and the European species. The same techniques define *Rattus/Mus* divergence at around 8–11 million years.

MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT)

Jerry R McGhee, The Immunobiology Vaccine Center, University of Alabama at Birmingham, Birmingham, Alabama, USA

The mammalian mucosal immune system is an integrated network of tissues, lymphoid and constitutive cells and effector molecules which protect the host from infection of the mucous membrane surfaces. This signifies a major difference from the peripheral immune system, where lymphoid cells and effector molecules are confined to lymph nodes and spleen, and communication occurs by cell trafficking through the lymphatic and blood circulation. The mucosal immune system is anatomically and functionally divided into sites where foreign antigens are encountered and are selectively taken up for initiation of immune responses, and sites where a more diffuse collection of B and T lymphocytes, differentiated plasma cells, macrophages and other antigen-presenting cells (APCs), as well as mast cells constitute effector tissues for mucosal immunity.

The term mucosa-associated lymphoid tissue (MALT) grew out of a knowledge base which suggested that ingested antigens were taken up into organized lymphoid tissues in the gastrointestinal tract, i.e. the gut-associated lymphoid tissue (GALT). This knowledge was extended by the realization that bronchus-associated lymphoid tissue (BALT) of experimental animals also contained precursors of immunoglobulin A (IgA) plasma cells. Thus, approximately 20 years ago the experimental evidence suggested that BALT and GALT, which collectively represent MALT, were major sites for provision of precursors of effector T and B cells for a common mucosal immunity in all effector sites. We now realize that this mucosal immune network is even more highly integrated and is finely regulated. The outcome of mucosal tissue encounters with foreign antigens and pathogens can range from mucosal secretory IgA (S-IgA), serum antibody responses and T cell-mediated immunity, to systemic anergy to orally or intranasally administered

antigen, a response commonly termed mucosal tolerance.

Organization of the mucosal immune system

In order to understand how mucosal immunity occurs, it is important to appreciate that foreign antigens, allergens and microbial pathogens are encountered either through ingestion or by inhalation. The mammalian host has thus evolved organized secondary lymphoid tissues in these regions, which facilitate antigen uptake for processing and presentation for ultimate induction of mucosal immune responses. In mice, rats and rabbits (among others), a distinct BALT occurs which appears to take up and respond to intranasal/inhaled antigens; however in humans, BALT does not develop and the major inductive tissues appear to be the palatine tonsils and adenoids (nasopharyngeal tonsils), which together form a physical barrier of lymphoid tissues termed Waldeyer's ring. Thus, we now more frequently describe tonsils and adenoids as nasal-associated lymphoid tissue (NALT) and assume that NALT are major inductive sites for intranasal/inhaled antigens. Likewise, we assume that GALT and especially the Peyer's patches are major inductive sites in the gastrointestinal tract so that collectively, MALT consists of NALT and GALT in humans and of NALT, BALT and GALT in experimental mammalian systems. These MALT inductive sites contain B and T lymphocytes which respond, in the presence of appropriate APCs, to the encountered antigen by developing into effector and memory B and T cells. These antigen-specific B and T cell populations then migrate from the inductive environment via lymphatic drainage, circulate through the bloodstream and home to mucosal effector regions. Thus, mucosal effector sites

include the more diffuse tissues where antigen-specific T and B lymphocytes ultimately reside and perform their respective functions (i.e. cytotoxicity, cytokine production or antibody synthesis) to protect mucosal surfaces.

Functional anatomy of NALT and GALT

The human tonsils and NALT

The human tonsils are the most accessible secondary lymphoid tissue for study, and as such, we know a great deal about the component cells. However, the palatine and nasopharyngeal (adenoids) tonsils are largely covered by a squamous epithelium and thus they are often not appreciated as mucosal tissues. Nevertheless, the palatine tonsils usually contain 10–20 crypts which increase their surface area. The deeper regions of these crypts contain microfold (M) cells which appear to take up encountered antigens (Figure 1). In addition, evidence for antigen presentation by epithelial cells which are class II positive (HLA-DR⁺) has been put forth; however their precise role in antigen presentation has not been documented to date. The tonsils contain all major classes of APCs including dendritic cell types, Langerhans cells, macrophages, class II⁺ B cells and antigen-retaining, follicular dendritic cells in germinal centers (Figure 1). A significant number of studies have shown that tonsillar APCs induce T cell proliferative and cytokine responses following *in vitro* stimulation with appropriate vaccines such as tetanus and diphtheria toxoid and purified protein derivative (PPD).

Approximately 50% of tonsillar cells are B lymphocytes which mainly occur in follicles containing germinal centers. Most tonsillar B cells are surface IgG positive (sIgG⁺); although significant numbers of sIgM⁺ and sIgA⁺ B cells are also found. Nevertheless, it is difficult to describe the tonsils as only a mucosal IgA inductive site, due to the presence of B

cells committed to other isotypes, especially for IgG subclasses. Approximately 40% of tonsillar cells are T cells and >98% of these express the $\alpha\beta$ T cell receptors (TCR). Somewhat higher ratios of CD4:CD8 cells are found in tonsils (3:1) when compared with peripheral blood (~1.5:1). In summary, the tonsils clearly have features of mucosal inductive sites; however their role in host mucosal immunity following intranasal immunization is not fully established.

Peyer's patches and GALT

The GALT is well-developed in most mammalian species and has been especially well-studied in rabbits and mice. GALT includes: 1) the Peyer's patches (PP), which are distinct nodules found mainly in the small intestine (10–12 in mice), and 2) the appendix, which is most pronounced in rabbits and humans. Mammals also contain solitary lymphoid nodules (SLN), smaller follicles throughout the small intestine and colon which, because of their morphologic similarities to PP, may represent more microscopic IgA inductive sites. Although the PPs, appendix and SLNs share similarities such as a dome region containing a specialized epithelium, important differences exist. The appendix, for example, has a less developed parafollicular region (T cell zone, Figure 2) than PPs, and the relative proportions of B cell subsets isolated from the appendix differ in numbers of sIgA⁺, sIgG⁺ and sIgM⁺ cells from B cell subsets obtained from PPs. Generally, most studies with GALT cells have been done with PPs, because it is assumed that the PPs are the major component of GALT. More studies are required to verify that this assumption is correct.

Discovered by Peyer in 1677 in human intestines, PPs were shown by Cornes in 1965 to develop during gestation, reach maximum numbers at puberty (>200), and decline slowly with age. PPs, present in

Figure 1 The potential role of NALT for development of mucosal immunity. A palatine tonsil with deep crypts illustrates the microanatomy. The cartoon portion shows the major APCs (LC, Langerhans cells; MØ, macrophages; FDC, follicular dendritic cells), B cell germinal centers and parafollicular T cell-dependent areas (TDA). Effector/memory lymphocyte homing occurs via the common mucosal immune system (CMIS).

Figure 2 The role of MALT in the induction of mucosal IgA responses. Antigen uptake by M cells occurs in GALT and NALT (MALT) and results in the initial induction of the immune response. Antigen-sensitized, precursor sIgA⁺ B cells and CD4⁺ T helper cells leave via efferent lymphatics and migrate to mesenteric lymph nodes (MLN) and then into the thoracic duct (TD) to reach the bloodstream. These migrating cells enter the IgA effector sites where terminal differentiation, synthesis and transport of S-IgA occurs. This induction in MALT and exodus of cells to effector sites is termed the common mucosal immune system.

all experimental animals, have been described in some detail in rabbits, mice and rats and to a lesser degree in swine, calves, dogs, goats and in subhuman primates. Not only is it likely that all mammalian species have PPs as IgA inductive sites, some studies have also suggested that avian species exhibit PP-like structures, which may also function as IgA inductive sites.

An important feature of PPs is the epithelium covering the dome region. This epithelium, which consists of cuboidal (not columnar) epithelial cells and a few goblet cells, contains little mucus to impede antigen uptake. Lymphocytes lie next to the epithelium, leading to the term follicle-associated epithelium (FAE). Specialized antigen-sampling cells, the M cells, are found in this FAE and also occur in appendix, SLNs and NALT (Figure 1). M cells exhibit short microvilli, small cytoplasmic vesicles, and thin extensions around the lymphoid cells in the lymphoepithelium. They can actively pinocytose proteins or phagocytose particular antigens, including virions, bacteria, and even small parasites. Because uptake of antigen does not result in degradation in lysosomes, the intact antigen can reach underlying lymphoreticular cells, including those which present antigen (Figure 2). In some instances, pathogenic viruses and bacteria enter the host by passing through M cells to reach systemic tissues, a process termed translocation. Thus, the M cell, in the absence of a mucus layer, serves as an antigen-sampling mechanism for uptake from the gut lumen. It is unlikely that M cells

actually present antigen in a class I or class II restricted sense, since they usually do not express major histocompatibility complex (MHC) class II determinants; however, they are important for antigen delivery to underlying APCs for induction of immune responses. More studies are required to determine the cellular origin of M cells and to understand the regulation of their function by cytokines and microbial cell products.

The PPs are divisible into three regions: 1) the dome, 2) the follicles with germinal centers (B cell zone), and 3) the parafoallicular or T cell-dependent area (T cell zone) (Figure 2). Mucosal lymphocytes enter the PPs through high endothelial venules (HEV) in the parafoallicular region (see mucosal lymphocyte homing below) and all cells exit the tissue via efferent lymphatics which drain into the mesenteric lymph nodes (MLN) (Figure 2). Each PP region contains a unique array of cells. The dome contains B and T cells with significant numbers of macrophages and small numbers of plasma cells. The B cell follicles normally exhibit 1–2 germinal centers, which are enriched in sIgA⁺ B cells and in which there is continual B cell class switching to IgA. The T cell zone possesses MHC class II⁺ antigen-presenting, dendritic cells. The PPs, which are less well-developed at birth, are first populated by T cells from the thymus and only later do distinct B cell zones develop. These B cell zones are dependent upon the gut microflora, since germ-free animals exhibit poorly developed PPs with no germinal centers.

Disassociated PP cells

The use of enzymatic procedures has allowed the isolation of presumably all major lymphoreticular cells from murine PPs. This analysis has shown that ~40% (or more) of isolated cells are of B lineage and ~35% are mature T cells of various subsets (Figure 2). Most isolated B cells are sIgM⁺; however, higher numbers of sIgA⁺ B cells occur (5–8%) than are seen in other secondary lymphoid tissues. Two major cytokines, interleukin 4 (IL-4) and tumor growth factor β (TGF β), have been shown to induce activated sIgM⁺ B cells to switch to downstream isotypes and TGF β has been most effective for switches to IgA. This cytokine induces $\mu \rightarrow \alpha$ switches in mice and to $\alpha 1$ and $\alpha 2$ in humans; the actual switches are preceded by induction of sterile α transcripts. Elegant studies have also provided direct evidence that somatic mutations occur during germinal center responses under control of T helper cells, a time when antigen-specific B cells form high-affinity Ig receptors. Presumably, isotype switches to IgA take place in NALT and GALT; however *in vivo* evidence that T helper cells/cytokines play a role in germinal center B cell switches to IgA have yet to be demonstrated. A significant number of PP B cells are dividing, which is consistent with the prominent germinal centers and continuous influx of environmental antigens into the PPs. Further, this explains why the PPs are major IgA inductive sites for response to locally encountered antigen, but does not explain why the dividing B cells fail to differentiate terminally into IgA (and other isotype)-producing plasma cells in the PPs themselves.

The IgA response is T cell-dependent and the PPs contain significant numbers of T cells. The majority of isolated CD3⁺ TCR⁺ T cells are CD4⁺ and exhibit the characteristics of T helper cells; however, CD3⁺, CD8⁺ T cells also occur with cytotoxic functions. For example, immunization of gut segments with reovirus results in the induction of CD8⁺ cytotoxic T lymphocytes (CTLs). Two major types of CD4⁺ T cells have been isolated and cloned from PPs. One type induced sIgM⁺ to sIgA⁺ B cell switches whilst the other preferentially supported IgA synthesis.

T_H2 cytokines, e.g. IL-5, IL-6 and IL-10, are of particular importance for inducing sIgA⁺ B cells to differentiate into IgA-producing plasma cells. In this regard, IL-6-induced high IgA responses *in vitro* in both mouse and human systems, and mice with targeted disruption of the IL-6 gene showed greatly reduced numbers of IgA plasma cells. One would predict from these observations that higher frequencies of T_H2 cytokine-producing T cells may occur in mucosal effector sites; however, as discussed

below it has been difficult to activate isolated lamina propria CD4⁺ T cells.

All major types of APCs also occur in significant numbers in the various PP regions. Macrophages, including both classical and tingible body types associated with uptake of apoptotic cells, are found in the dome region and germinal centers, respectively. The T cell zones are enriched in dendritic cells (DC), which have been shown in functional assays to form clusters with CD4⁺ T cells that are adept in supporting IgA synthesis. No studies have addressed the role of APCs in the three major PP regions, i.e. the dome, T or B zones after M cell uptake, and especially whether the B cells (which express MHC class II) can function in this capacity. The role of persistent antigen could be important for the generation of sIgA⁺B and CD4⁺ T helper cell responses in Peyer's patches. In this regard, it is well-established that follicular dendritic cells (FDC) in B cell areas of the tonsils can retain native antigen, usually via antigen-antibody complexes. The slow release of these complexes may be important for stimulation and expansion of antigen-specific B cell clones. The Peyer's patch contains FDCs, and these cells may serve a similar role in this IgA inductive site; however, more studies will be required to determine the possible role for persistent antigen and IgA immune complexes in these mucosal inductive sites. Antigen trapped by FDCs (as immune complexes) is released in the form of immune complex coated bodies (iccosomes). Specific germinal center (GC) B cells find iccosomes remarkably palatable and endocytose them. Iccosomal antigen is then processed with great efficiency and is presented to T cells. The antigen, or possibly IgA immune complexes, may associate with FDCs in the GC and release iccosomes for prolonged periods. This slow release may be sufficient to allow selective induction of antigen-specific CD4⁺ T helper and sIgA⁺ B cells in the Peyer's patches. A second encounter with antigen would result in expansion of CD4⁺ T helper cells and increased IgA responses in mucosal effector tissues.

Mucosal lymphocyte homing

Lymphocytes of B and T lineages recirculate via the bloodstream and re-enter secondary lymphoid tissues. This lymphocyte homing of naive cells insures that a diverse repertoire exists in mucosal and peripheral lymphoid tissues, while homing of memory and effector cells is responsible for keeping lymphocytes compartmentalized, i.e. mucosal in the mucosa and peripheral in the periphery. It is now clear that lymphocytes leave the blood and enter lymphoid compartments (usually via HEVs) in a

multistep extravasation process. Homing is dependent upon the expression of adhesion molecules such as selectins and integrins, collectively termed 'homing receptors' on lymphocytes, with specific ligands on HEV and venule endothelial cells which are collectively termed 'addressins'.

Some generalizations can be made to this rapidly changing area. First, naive T and B lymphocytes can express homing receptors for addressins on either peripheral or mucosal inductive tissues, i.e. peripheral lymph nodes versus Peyer's patches. It is generally accepted that naive lymphocytes can recirculate between secondary lymphoid tissues; however only memory or effector lymphocytes have receptor-ligands for movement into certain microenvironments such as lamina propria or the epithelium of the intestinal mucosa. Peripheral lymphocyte homing is mainly controlled by expression of L-selectin and the ligand peripheral lymph node addressin (PNAd); however, other receptors and ligands are also involved. Naive mucosal lymphocytes express β_7 -integrin family members, particularly $\alpha_4\beta_7$. Peyer's patch HEVs and gastrointestinal tract lamina propria express the mucosal addressin cell adhesion molecule (MAdCAM-1) which serves as the specific ligand for $\alpha_4\beta_7$. Interestingly, mucosa-derived memory lymphocytes express higher levels of $\alpha_4\beta_7$, which presumably allows for binding to MAdCAM-1 on PP HEVs as well as to the low level expression of this addressin on lamina propria venules in the gastrointestinal tract. Although $\alpha_4\beta_7$ -MAdCAM-1 are the major receptor-ligand for mucosal homing in the gastrointestinal tract, other receptor-ligand combinations are also involved.

A second β_7 -integrin, $\alpha_E\beta_7$ is expressed on >98% of human intraepithelial lymphocytes (IELs, see below) and the ligand for this homing receptor is E-cadherin expressed on the basolateral portion of epithelial cells. It has been shown that TGF β markedly enhances the expression of $\alpha_E\beta_7$ on IELs, and thus promotes their increased adherence to epithelial cells.

Perhaps the most intriguing aspect of mucosal lymphocyte homing is that no lung-specific integrins have yet been identified. Further, the homing receptors present on BALT (in rabbits) and NALT (in humans) which directs mucosal lymphocytes to other regions, e.g. the lungs and the genitourinary tract, remain to be fully defined. Nevertheless, it is known that intranasal immunization is quite effective for induction of mucosal IgA responses in the upper respiratory and the female reproductive tracts. It is tempting to suggest that NALT lymphocytes bear homing receptors for addressins expressed in these mucosal effector sites. Clearly other integrins and addressins may be involved and may ultimately

explain how MALT cells from NALT redistribute more frequently to certain effector sites, while GALT repopulate common as well as different mucosal effector sites.

Mucosal effector sites

It is known that local application of antigen on to mucosal tissues or direct injection into exocrine glands can result in the production of S-IgA antibodies at that site. This local response often requires the use of adjuvants, results in an influx of inflammatory cells, and subsequently leads to the production of antibodies (of IgG, IgM and IgA isotypes) in the serum. It is likely that this local stimulation results in an accumulation of clonal B and T helper cells (from MALT ?) and that cognate interactions induce the terminal differentiation of IgA plasma cells and local S-IgA responses. The leakage of antigen-adjuvant from local mucosal sites and their entrapment in systemic lymphoid tissues probably accounts for the serum antibody response. However, it is important to emphasize that in humans the serum IgA (largely monomeric IgA1) is derived from the bone marrow, spleen and peripheral lymph nodes. Further, >98% of S-IgA antibodies present in human external secretions (principally as dimeric IgA1 and IgA2 subclasses) are locally produced by plasma cells in mucosal tissues. The polymeric IgA (with J chain) is selectively transported by the polymeric Ig receptor secretory component (SC) that has been produced by epithelial and ductal cells and is released at the luminal surface as a polymeric IgA molecule containing J chain and SC.

The best-studied effector sites are the lamina propria (LP) and the intraepithelial lymphocyte (IEL) compartments in the gastrointestinal tract. Interestingly, the LP of the gastrointestinal tract is the only tissue where large numbers of plasma cells occur under normal physiological conditions. Seventy to ninety per cent of these plasma cells are of the IgA isotype and daily IgA production in the human adult is estimated at 3–4 g per day. In the mouse, the average lifespan of these cells is approximately 5–9 days, and thus these cells must be continuously replaced, presumably by GALT-derived precursors. It is generally assumed that migrating, sIgA⁺ B cells rapidly differentiate into IgA plasma cells in the presence of T cell and cytokine help.

Estimates of the percentage of T cells amongst LP lymphocytes range from 40 to 90% and this wide range is most likely due to the different techniques used to identify cells (*in situ* immunohistochemical staining versus analysis of isolated cells prepared by enzymatic digestion). The majority of CD3⁺ T cells

in the LP (65–80%) are CD4⁺, again consistent with the observation that the LP is the major site of T helper cell-regulated IgA synthesis. The LP T cells demonstrate lower proliferative responses to T cell mitogens when compared to T cells from lymphoid tissues or the peripheral blood; however, these T cells proliferate spontaneously when cultured in the presence of IL-2, and LP T cells spontaneously secrete cytokines. These observations are consistent with the hypothesis that LP T cells are activated *in vivo*. More studies are needed to fully characterize the lymphoid cells present in the LP of the gastrointestinal tract. The role of MHC class II⁺ B cells and macrophages in the activation of CD4⁺ T cells in this region should also receive more emphasis. Further, the mechanisms whereby T cells provide help for the terminal differentiation events for B cells is another area for study. In spite of the difficulties in enzymatic isolation of functional cells and in triggering T cells, this will no doubt be a major focus of future studies in the mucosal immune system.

Intraepithelial lymphocytes

Intraepithelial lymphocytes (IELs) reside between intestinal epithelial cells and are the first cells to contact luminal antigen that crosses the mucosa in an M cell-independent manner. This heterogeneous population of mainly T cells comprises a very large number of cells (more than half the number of T cells in peripheral organs) but their function remains poorly understood. The majority of murine IELs (80%) are CD3⁺, and over 75% of these also express CD8. In mice and chickens, significant numbers of $\gamma\delta$ TCR⁺ IELs are found (40–60%) in addition to $\alpha\beta$ TCR⁺ cells; however, this number varies with mouse strain, age and housing conditions. The $\gamma\delta$ TCR⁺ IELs represent a minor component of human IELs (~15%) under normal conditions, but significantly increase under certain conditions, such as celiac disease.

The physiological role of IELs is poorly understood; however, several functions for these cells have been described and this diversity is consistent with their phenotypic heterogeneity. IELs have been shown to mediate antigen-specific delayed-type hypersensitivity (DTH) responses, to exhibit virus-specific CTL function, to express natural killer (NK)-like activity and to produce a local graft-versus-host reaction (GVHR) when transferred to semiallogeneic hosts. IELs respond poorly to conventional T cell mitogens when compared to splenic T cells; however, there is evidence that human IELs are induced to proliferate via a CD2 pathway rather than through stimulation of the CD3–TCR complex. With regard to regulation of humoral immunity, $\gamma\delta$ TCR⁺ IEL T

cells have been shown to abrogate the induction of mucosal tolerance, while $\alpha\beta$ TCR⁺ IEL T cells provide help for production of IgA. Interestingly, the targeted disruption of the δ chain of TCR in mice results in a lack of $\gamma\delta$ T cells among IELs and in a mucosal IgA deficiency, suggesting that $\gamma\delta$ T cells may upregulate CD4⁺ T helper cells for mucosal immunity. IELs can be induced to produce a variety of cytokines which are characteristically produced by T_H1- and T_H2-type cells and $\alpha\beta$ TCR⁺ IELs can also provide help for B cell responses.

The common mucosal immune system

Studies in humans have also shown that orally administered antigen results in the presence of S-IgA antibodies in remote external secretions. For example, studies have shown that ingestion of killed bacterial vaccines, i.e. *Streptococcus mutans* or *Vibrio cholerae* plus cholera toxin B subunit (CT-B), induce specific S-IgA antibodies in external secretions but not in serum. Mitogen stimulation of human peripheral blood lymphocytes results in the synthesis of polymeric IgA (serum IgA is mostly monomeric) and in the induction of both IgA1 and IgA2 plasma cells. Further, the peripheral blood B cells of human volunteers ingesting bacterial vaccines produced specific IgA antibodies, suggesting that they were in a mucosal homing pathway. In fact, studies with several viral and other bacterial vaccines have clearly shown the subsequent presence of S-IgA antibodies in various human external secretions.

Equally compelling work in experimental animals is providing evidence that intranasal immunization is a particularly effective way to induce mucosal S-IgA as well as serum antibody responses. In these studies, less vaccine antigen and mucosal adjuvant is required for induction of effective mucosal immunity. Further, intranasal immunization appears to be particularly effective for induction of S-IgA antibodies in nasal washes, saliva, tears and in general nongastrointestinal external secretions. It is intriguing that this route of immunization is particularly effective in priming for genitourinary tract responses, and offers promise for development of vaccines to prevent sexually transmitted diseases.

In summary, mammals possess a common mucosal immune system, in which antigen stimulation of MALT induces an exodus of specific lymphocytes which home to the various mucosal effector sites (Figures 1 and 2). These responses are finely regulated and T cells and cytokines are of central importance for ultimate plasma cell differentiation and production of S-IgA antibodies in external secretions. The current need for vaccines, including the universal

efforts to develop immunity to human immunodeficiency virus (HIV), compels us to increase our understanding of how we can use the common mucosal immune system to advantage for the ultimate prevention of infectious diseases at mucosal sites.

MUCOSAL IMMUNITY

Stephen P James, Division of Gastroenterology, Department of Medicine, University of Maryland at Baltimore and Baltimore VA Medical Center, Baltimore, Maryland, USA

The mucosal immune system is comprised of specialized structures and sites, including Peyer's patches, bronchus-associated lymphoid tissue (BALT), local draining lymph nodes, and the lamina propria and epithelium, that contain a complex mixture of cells that undergo continuous activation, migration and homing, and terminal differentiation and effector functions including release of antibodies and numerous mediators. This complicated system has evolved under two apposing evolutionary pressures, on the one hand to provide the host with protective mechanisms against invasion by potential pathogens, such as bacteria, viruses and protozoans, across mucosal surfaces, and on the other hand the equally necessary function of permitting immunological tolerance against the wide array of harmless environmental antigens and products of normal digestion and the normal intestinal flora.

Nonimmunological host defense factors

Nonspecific and specific immune mechanisms in the gastrointestinal tract function in concert with other nonimmunological mechanisms to protect the host. The main effect of all of these factors is to limit the growth of organisms in the gastrointestinal tract and prevent entry of pathogens across the mucosa. The normal motor propulsive activity of the gastrointestinal tract is also crucial in limiting the growth of organisms in the small intestine. In addition, the release of mediators by mast cells that increase intestinal contractility is thought to be a primary mechanism of expulsion of pathogens in intestinal parasitic infections. Mucin is thought to be protective for the mucosa. The effect of mucus may be to bind and trap bacteria, thus limiting their interaction with epithelial cells. In the colon, the presence of a normal flora is thought to limit, through multiple mechanisms, the overgrowth of pathogens. Lactoperoxidase is released into the intestinal lumen, and it may act in concert with immune factors such

as immunoglobulin A (IgA) to limit the growth of pathogens. Recently, gastrointestinal Paneth cells have been shown to produce a class of defensin molecules named cryptdins. These molecules have a unique structure and have antibacterial properties, among others. All of these mechanisms are to some extent redundant, so that an alteration or absence of one of them, such as gastric acid, may not lead to any obvious pathological consequences if other mechanisms remain intact.

Structural organization of the mucosal immune system

Lymphocytes associated with mucosal sites are located in three major compartments: 1) organized tissue such as the Peyer's patches, BALT, tonsils, mesenteric lymph nodes and appendix; 2) the nonorganized lymphoid cells present diffusely throughout the lamina propria; and 3) the lymphocytes present within the mucosal epithelium, the intraepithelial lymphocytes (IELs). Lymphoid cells in organized structures such as the Peyer's patches are thought to be primarily less mature cells that play an important role in initiation of immune responses, i.e. they carry out functions of the 'afferent' limb of the immune response due to their interaction with antigens traversing the specialized M cell epithelium of these sites. On the other hand, lymphocytes in the diffuse lamina propria compartment are more mature cells, many of which are activated, that are thought to carry out effector functions, such as IgA production. The function of intraepithelial lymphocytes *in vivo* is uncertain, although their phenotypic and functional characteristics *in vitro* suggest that they also carry out host defense effector functions and may also have important interactions with enterocytes.

Organized mucosal lymphoid tissue

It has been estimated that about 10% of lymphoid cells in humans are associated with the organized lymphoid structures of the gastrointestinal tract. Peyer's patches are located throughout the jejunum and ileum of humans, being most concentrated in the terminal ileum. Lymphoid aggregates are also found in the colon, particularly in the rectum, however they differ from the typical small bowel aggregates in having relatively few activated B cell germinal centers. Peyer's patches and lymphoid aggregates are well developed in fetal life, but germinal centers do not appear until after birth, presumably due to the initiation of stimulation from food antigens and bacteria. This is supported by the observation that germ-free animals do not develop germinal centers. The number of Peyer's patches increases to about 250

during adolescence; their numbers decline rapidly initially after puberty, and then gradually, numbering about 100 in elderly individuals. The Peyer's patches are characterized by the presence of a specialized epithelium which contains M cells. M Cells appear during fetal life along with subepithelial lymphocytes. These cells are interspersed among absorptive epithelial cells covering the dome of the Peyer's patch on the luminal side. In contrast to the microvilli present on absorptive cells, M cells have only occasional short microvilli on their surface and short ridge-like folds. M Cells are actively pinocytotic and it appears that they transport much of what they take up to the underlying subepithelial lymphoid cells. This has led to the concept that they provide a critical sampling process of the contents of the intestinal lumen that allows the mucosal immune system to continuously sample the luminal contents. Many different types of macromolecules, particles and intact pathogens, including bacteria, viruses and protozoans, have been shown to be taken up by M cells. Small molecules may also cross the M cell by fluid phase endocytosis.

The nodules and germinal centers of Peyer's patches are composed primarily of B cells. The germinal centers contain central activated B cells and antigen-presenting cells and dendritic cells, and there is a surrounding dense layer of resting B cells. Adjacent to the germinal centers are interfollicular zones that contain predominantly CD4 T cells. The T cells of the Peyer's patch are thymic dependent, as demonstrated by the fact that thymectomy depletes cells from the interfollicular zone of the Peyer's patch. B Cells in the germinal center are enriched in surface IgA-positive cells. However, IgA-positive B cells are only a minority of B cells present in this site, and there is evidence that Peyer's patch germinal center B cells undergo immunoglobulin class switching to the IgA phenotype. Cells activated in the Peyer's patch do not mature into immunoglobulin secreting cells in this site; rather, once activated, they migrate to mesenteric lymph nodes, undergo further division, and home back to the lamina propria where terminal differentiation into IgA-secreting plasma cells occurs.

Functional antigen-presenting cells are present in the Peyer's patches. Dendritic cells and macrophages are present directly beneath the epithelium of the Peyer's patch where they are likely to be the first cells to encounter antigens transported by M cells. Antigen-presenting cells are also present in the germinal centers and interfollicular areas. Both cell types are capable of antigen presentation, and both may also carry out other roles via cytokine production. In particular, dendritic cells may play an important role in class switch of B cells towards IgA commitment.

Diffusely distributed mucosal lymphoid cells

The nonorganized lymphoid cell compartment located diffusely within and beneath the mucosal epithelium contains a large, complex mixture of cells that are thought to play an essential role in immune effector functions in the gastrointestinal tract. The lamina propria contains a large number of T cells, B cells and plasma cells, macrophages, mast cells and smaller numbers of eosinophils, neutrophils and dendritic cells. About 80–90% of the B cells and plasma cells in the normal gastrointestinal tract are IgA positive. Most of the non-IgA committed cells are IgM-positive, with about 1–2% each of IgG- and IgE-positive cells. About one-third of the cells in the lamina propria are T cells, and while representing a heterogeneous group of cells, they also have features that distinguish them from the systemic immune system.

Mucosal T cells

The effector functions mediated by lymphoid cells in the lamina propria are probably essential for effective host defense against pathogens. T cells are found in the epithelial layer (intraepithelial lymphocytes, see below) and in the loose connective tissue compartment of the lamina propria. Due to the large size of the intestine, the intestinal lamina propria represents the largest T cell site in mammals, and particularly in humans. A significant number of T cells in the intestinal mucosa are activated. The phenotypic distribution of CD4 and CD8 T cells is similar to that of peripheral blood. T cells in the intestinal lamina propria have almost exclusively the CD45RA low (in humans and primates) and CD45RB low (in rodents) phenotypes that are typically found on 'memory' lymphocytes. Although lamina propria T cells appear to only infrequently undergo proliferation, their activation can lead to high levels of cytokine gene expression. Most T cells in the human lamina propria express either CD4 or CD8 and $\alpha\beta$ T cell receptors (TCRs), suggesting that they have arisen from the bone marrow and undergone prior thymic education. The TCR repertoire of lamina propria T cells is very diverse, and is not limited as it is in the epithelium and certain other sites.

Intraepithelial lymphocytes

The intestinal mucosa contains a specialized subset of lymphocytes that are interspersed within the epithelial layer and referred to as intraepithelial lymphocytes (IELs). While the major physiological functions of these cells is still uncertain, a number of possibilities are under active study, including their role in host defense as cytolytic cells and their

response to antigens presented on the surface of adjacent epithelial cells. It is possible that IELs and epithelial cells may interact in ways that modify each other's functions. The IEL subpopulation of cells in both mice and humans is phenotypically pleomorphic, but certain features characterize this subset: in humans the majority of cells are CD8⁺, CD3⁺ and have a large granular lymphocyte morphology. In addition, while the majority in humans have $\alpha\beta$ T cell receptors, there is an increased proportion of cells having $\gamma\delta$ receptors that are rare in the peripheral circulation. In mice, many of the cells are Thy-1 negative, and a substantially greater proportion of IELs have $\gamma\delta$ T cell receptors, although this proportion seems to be highly variable, depending on environmental factors such as the presence or absence of pathogens in the animal colonies. In humans, an increased proportion of IELs express activation markers such as CD25 compared to peripheral blood, and a high proportion express the $\alpha_E\beta_7$ -integrin adhesion molecule. Interestingly, it is difficult to maximally activate IEL proliferation *in vitro* with mitogens or anti-CD3 alone; however, these cells can exhibit high proliferation when triggered through CD2 by using sheep erythrocytes or combinations of anti-CD2 monoclonal antibodies. These results clearly indicate that these lymphoid cells may require special types of cell–cell interactions for triggering.

B cells in mucosal immunity

The gastrointestinal mucosa is characterized by a great preponderance of IgA B cells and IgA-secreting plasma cells. There is evidence that exogenous factors, including T cell cytokines such as transforming growth factor β (TGF β), play a role in class switching to IgA. However, the understanding of this event is still incomplete. Furthermore, the site at which class switching of these cells occurs is still unknown. Clearly, the bone marrow is a major site of IgA production and this event can occur in that site. Although the Peyer's patches are enriched in IgA-bearing cells, it has also been thought that IgA switch may be occurring in this site. The events that control the maturation of IgA B cells into IgA-secreting plasma cells is better understood. Although B cells can respond to soluble antigens in the absence of antigen-presenting cells, for many antigens the process of terminal differentiation into plasma cells requires T cell 'help'. The factors provided by T cells include cytokines that act in synergy, including interleukin 2 (IL-2), IL-4, IL-5, IL-6 and interferon γ (IFN γ). In addition, it seems likely, although not proved, that cell contact between T and B cells may

provide additional 'cognate' interactions that augment IgA B cell differentiation.

Mucosal mast cells

Mast cells are derived from the bone marrow and migrate to tissue sites throughout the body. There is evidence in animal models that connective tissue mast cells differ in a number of ways from mast cells found in mucosal sites, such as in having relatively little heparin and the serine protease chymase. Mast cells are numerous in the gastrointestinal submucosa, often being found in close proximity to blood vessels, although they are often not recognized unless special stains are used for histological examination. Mast cells contain numerous preformed mediators, such as histamine, proteoglycans and serine proteases, and have the ability to synthesize numerous other inflammatory mediators such as prostaglandins, leukotrienes, platelet-activating factor (PAF) and cytokines, including IL-3, IL-4, IL-5, IL-6 and granulocyte-macrophage colony-stimulating factor (GM-CSF). Mast cells have high-affinity IgE receptors, so that in tissue sites they may be 'armed' by the presence of preformed IgE with specific antigen specificity. Upon encounter with antigen, the mast cell rapidly releases its preformed mediators and may synthesize others. The mediators produced by mast cells have a wide range of physiological and pathophysiological effects both on the immune system and elsewhere. Thus, for example, during intestinal parasite infection mast cell products may contribute to

increased intestinal motility and fluid and electrolyte transport that is important in host defense.

Regulation of lymphocyte recirculation to the mucosa (homing)

An important characteristic of the immune system and the mucosal immune system in particular is the mobility of its cellular components. B cells and T cells originate in the bone marrow and thymus and migrate to the Peyer's patches (Figure 1). Upon stimulation by antigens or pathogens, cells either become tolerized or become activated, upon which they migrate to mesenteric lymph nodes, whereupon they enter the systemic immune system to recirculate. Cells that have been stimulated in the mucosal immune system have a tendency to recirculate to the sites where they were stimulated (homing), which allows the mucosal immune system to be repopulated with cells having memory for gut antigens and with cells that can mediate effector functions against pathogens on rechallenge. Because cells that are stimulated in the gastrointestinal tract can also recirculate to other mucosal sites, such as those of the lung, lactating breast and genitourinary tract, the concept of a 'common mucosal immune' system has been postulated. Although there is only partial cross-over of lymphocytes from the pulmonary and genitourinary system, this notion is important because it suggests the possibility that general protective immunity at mucosal sites could possibly be gener-

Figure 1 Origin and recirculation of mucosal lymphocytes. Most if not all lymphoid cells in the gastrointestinal tract originate in the bone marrow. B cells migrate to Peyer's patches, where they tend to undergo further commitment to the IgA lineage. T cells undergo thymic education and then migrate to Peyer's patches and may also undergo specialized differentiation. A small subpopulation of T cells, those bearing $\gamma\delta$ T cell receptors, have a propensity to migrate to the intestinal epithelium. Cells that are activated in the Peyer's patch probably leave the patch soon after activation and undergo further rounds of proliferation in mesenteric lymph nodes. Cells that have been activated in the Peyer's patches have a tendency to migrate back to or 'home' to mucosal surfaces, particularly of the gastrointestinal tract.

Figure 2 IgA in serum and secretions are different. IgA in serum is predominantly the product of bone marrow cells, there is more IgA1 than IgA2, it is produced at a rate of about 1.2 g day⁻¹ and is monomeric. In contrast, secretory IgA is produced primarily by intestinal plasma cells and contains J chain, also produced by plasma cells. There is more IgA2 than IgA1 and it is produced at a rate of about 3.2 g day⁻¹. Finally, IgA in secretions contains a portion of the receptor used for translocation across the epithelial cell, the polymeric immunoglobulin receptor (secretory component).

ated by use of an immunogenic oral vaccine. The best evidence for selective migration is for IgA B cells, but there are also some data to show that T cells may also undergo selective migration.

A number of cell surface adhesins appear to be important in homing. In particular the $\alpha_4\beta_7$ -integrin expressed on some activated lymphocytes seems to be a ligand for MAdCAM-1 (mucosal addressin cell adhesion molecule 1) expressed on mucosal endothelial cells. There is some evidence that L-selectin and $\alpha_4\beta_7$ -integrin may be synergistic for migration of lymphocytes into Peyer's patches. A second ligand, $\alpha_E\beta_7$ -integrin is highly expressed on intraepithelial lymphocytes and appears to be a receptor that is important for retention of lymphocytes in the gastrointestinal epithelium. Other relevant structures may include the fibronectin, vitronectin and hyaluronic acid receptors (CD44) on lymphoid cells, which allow the cell to adhere to components of the extracellular matrix. It is clear that these ligands on lymphocytes and endothelial cells are not static but are dynamically regulated by factors such as cytokines and inflammatory mediators.

IgA in mucosal host defense

IgA is quantitatively the most important of the immunoglobulins, having a synthetic rate exceeding that of all other immunoglobulins combined when secretory as well as circulating IgA is taken into account. In humans it is encoded by two genes within the immunoglobulin gene locus on chromosome 14. The 5' IgA gene encodes IgA1, the predominant circulating IgA and a major component of the IgA in mucosal secretions. The more 3' IgA gene encodes IgA2, the IgA that is particularly abundant in mucosal secretions. IgA1 differs from IgA2 in being susceptible to cleavage in its hinge region by proteases secreted by a number of different bacteria. Cleavage can lead to markedly reduced function.

Another difference between IgA1 and IgA2 is that the latter occurs in two allotypic forms, IgA2(m1) and IgA2(m2), which are distinguished from one another by the fact that IgA2(m1) lacks interchain (H-L) disulfide bonds. The IgA heavy chain, in common with the IgM heavy chain, has an extra cysteine residue in the C-terminal segment. This permits IgA to interact J (joining) chain to form IgA dimers and trimers. IgA polymerization is important to IgA function because polymerized IgA (pIgA) has an increased capacity to bind to and agglutinate antigens.

Polymeric immunoglobulin receptor (secretory component)

Only dimerized IgA and IgM can react with the polymeric immunoglobulin receptor (pIgR, secretory component, SC) produced by epithelial cells. pIgR acts as a transport receptor for IgA and becomes part of the secreted IgA molecule. It renders the IgA molecule less susceptible to proteolytic digestion and more mucophilic, thus enhancing the ability of the IgA molecule to interact with potential pathogens and to prevent their attachment to the epithelial surface. The sequence of events occurring during IgA transport involves first the binding of polymeric IgA to pIgR on the basolateral surface of the epithelial cell, followed by endocytosis of IgA into vesicles, movement of IgA-containing vesicles to the apical surface of the cell, and finally, release of IgA pIgR complexes into the mucosal lumen (Figure 2). This final step requires cleavage of the pIgR receptor molecule so that the receptor for IgA becomes part of the secreted IgA molecule. Cellular synthesis and translocation of pIgR is independent of the presence of IgA and usually exceeds the amount necessary for transport, leading to the secretion of free pIgR.

IgA transport mediated by pIgR occurs in the epithelium of the digestive tract, the salivary glands, the bronchial mucosa and the lactating mammary

glands. It also occurs in the uterine epithelium, where it is regulated by the effects of estrogen on pIgR synthesis by uterine epithelial cells. IgA transport mediated by pIgR also takes place in the liver, in which case it results in secretion of IgA into the bile. This involves the biliary epithelial cells, and in rodents, hepatocytes. Hepatic uptake of IgA may be one mechanism by which IgA secreted into the circulation is redirected back to the mucosa in species with well-developed pIgR-mediated hepatic transport capabilities, possibly to clear the circulation of potentially damaging antigenic material that has penetrated the mucosal barrier and become bound to circulating IgA.

Neuroimmune interactions with the mucosal immune system

There is substantial evidence indicating that the nervous system and immune system can interact in a variety of ways that modifies the function of each. Anatomically, the gut has a rich plexus of nerves that play a critical role in organization of gut motility, and are likely to be important in other functions such as regulation of epithelial cell function. Nerve fibers can be observed in close proximity of lymphoid cells in Peyer's patches and in the lamina propria. The major neuropeptide mediators of the enteric nervous system are substance P, vasoactive intestinal peptide (VIP) and somatostatin, and lymphoid cells have receptors for each of these transmitters. *In vitro*, each of these neurotransmitters has been shown to have the potential for modifying the response of lymphoid cells. The effects of these transmitters are complex, but in general, somatostatin and VIP inhibit proliferation and differentiation of lymphoid cells, whereas substance P is stimulatory. In addition, VIP has been shown to be chemotactic for monocytes and it may have an effect on the recirculation of lymphoid cells. These observations have obvious implications for the possible ability of the nervous system to modify immune responses. This possibility has been demonstrated *in vivo* in animal studies in which repeated conditioning with a simultaneous visual and antigenic stimulus eventually led to the ability to release mast cell products on stimulation with the visual signal alone. Conversely, leukocytes, including lymphocytes, monocytes and mast cells, have the ability to synthesize neuropeptides, and potentially during an immunological response it is possible that there may be direct feedback from the immune system to the nervous system.

Oral tolerance

When antigens are fed to adult animals or humans, for the most part there is little or no detectable response of the systemic immune system, and, usually, in the mucosal immune system. The mechanisms by which this occurs are uncertain, but undoubtedly it serves to prevent a massive response of the immune system to the large numbers of different potentially immunogenic food and bacterial antigens present in the intestinal lumen that would be deleterious to the host. The lack of response is variable and depends on the nature of the antigen. The lack of response is nearly complete for most food antigens, but there may be responses to complex antigens, particularly when present on live organisms such as bacterial pathogens and viruses. The exact mechanisms by which the immune system is able to distinguish a pathogen from commensal bacteria is unknown, but probably involves the ability of pathogens to attach to or invade the mucosa and induce inflammatory responses that lead to activation of the immune system.

There appear to be multiple different mechanisms that result in tolerance, including T cell deletion, both in the thymus and peripherally, and B cell deletion. In addition, there is good evidence in animal models that the mucosal immune system may generate suppressor cells, which may be either antigen specific or antigen nonspecific, that inhibit the generation of antibody responses in the systemic immune system. Interestingly, this mechanism sometimes permits the development of a local IgA response while inhibiting potentially inflammatory IgG responses. In addition to these mechanisms, T cells can be anergized by exposure to antigens in the absence of costimulatory molecules, which appears to result in a relatively permanent change in the signal transduction pathways in these cells.

MULTIPLE SCLEROSIS

Jef CM Raus, Multiple Sclerosis Research and Immunology,
Dr Wilems Institute, Diepenbeek, Belgium

Multiple sclerosis (MS) is the major human demyelinating disease of the central nervous system, affecting most commonly young adults. The disease is characterized by episodes of neurologic symptoms occurring over a period of days to weeks, followed by complete or incomplete remissions of various durations. Early symptoms of MS include fatigue, gait and limb ataxia, spasticity, dizziness, double vision, acute optic neuritis and numbness and weakness in one or more limbs. Depending on the progression of the disease, MS can be classified into several categories. Although these categories are not entirely distinct, for practical purposes MS can be classified as follows:

- Relapsing–remitting disease, defined as the occurrence of exacerbations with complete remission, leading to mild disability only with no overall change in daily functioning.
- Chronic relapsing disease (= relapsing progressive MS) characterized by exacerbations with incomplete remissions and greater disability with each attack.
- Chronic progressive disease, characterized by lack of remission accompanied by continued progressive disability.

Sixty-five per cent of MS patients have the relapsing–remitting form at onset, but more than 40% of these develop progressive MS later on. MS starts most commonly between 20 and 50 years of age and affects women more frequently than men.

The multiple sclerosis lesion

MS is characterized by multiple areas of myelin destruction in the central nervous system (CNS), known as plaques. CNS myelin is made by local oligodendrocytes that are gradually lost along the progression of the disease. Microscopic examination of the lesions or plaques indicates that demyelination is often accompanied by an active immune response. Inflammatory infiltrates are located perivenularly and the cellular composition of the infiltrates varies with the age of the lesions. Acute lesions consist of macrophages, lymphocytes, plasma cells and nonmyelinated axons, while the inflammatory infiltrates are less pronounced in the chronic plaques. Reactive gliosis and inefficient attempts at remyelination can also be observed, suggesting that the immunological mechanisms in more chronic lesions are different from those in acute lesions.

Studies of the experimental animal model for MS, experimental autoimmune encephalomyelitis (EAE), have demonstrated that myelin basic protein (MBP)-specific, proteolipid protein (PLP)-specific or myelin oligodendroglia glycoprotein (MOG)-specific T cells mediate the autoimmune pathogenesis. The encephalitogenic epitopes on myelin antigens differ between species and strains and are influenced by the major histocompatibility complex (MHC) make-up of the animal. Furthermore, in some strains the encephalitogenic T cells use a very limited set of T cell receptor (TCR) chains in the recognition of the com-

plex formed by disease-associated MHC class II molecules and encephalitogenic peptides. This has led to innovative therapeutic approaches targeting each of the components specifically. In the chronic-relapsing form of EAE in the SJL/J mouse, the disease exacerbates and remits as in MS, and the murine pathology strongly resembles that seen in humans. It is possible that MS, like EAE, is caused by T lymphocytes recognizing antigens found in the CNS. However, whether the therapeutic approaches successfully used in EAE will be effective in MS is not clear, since the relationship between a specific TCR and disease is not evident. Furthermore, to date no specific antigens for the inflammatory processes in MS have been described.

Oligoclonal bands in cerebrospinal fluid

The synthesis of immunoglobulins in the CNS of MS patients is increased. About 90% of MS patients show a limited number of distinct bands (= immunoglobulins), as observed by electrophoresis or isoelectric focusing. These so-called oligoclonal bands are used as a diagnostic aid for MS but are not specific for the disease. In contrast to infectious diseases such as syphilis, in which immunoglobulin production in the CNS is antigen-driven, the specificity of the increased CNS immunoglobulin synthesis is not known in MS. The increased production of immunoglobulins in MS may be caused by an as yet unidentified (infectious) agent or may be related to a defect in immune regulation. Indeed, evidence for an impaired immune regulation is provided by the increased reactivity of B cells which could be due to impaired suppression.

Autoantigen-specific T cell responses

Although the responsible autoantigens for the disease are unknown, it is widely accepted that MS is caused by disturbances in the regulation of autoantigen-specific T cells. It is also possible that more than one antigen is involved. Some of the most prominent candidate brain antigens are shown in Table 1.

MBP-specific CD4⁺ α/β T cell lines and clones can be generated from peripheral blood lymphocytes (PBLs) of MS patients and healthy individuals. The frequencies, fine specificities, restrictive HLA determinants and TCR usage are similar in both populations, but in MS patients a significantly higher proportion of these cells is in an activated state, which gives them a higher potential to cross the blood-brain barrier. In contrast to EAE, in MS a TCR heterogeneity can be seen among MBP-specific T cell clones from different individuals although there is a limited TCR-V β gene usage among MBP-specific T cell clones of the same individual. Furthermore, the predominant V β gene used by the studied MBP-specific T cell clones does not correlate with the epitope specificity of T cells nor with their restricting HLA molecule. The heterogeneity of MBP-specific T cell clones in MS patients is less pronounced than in healthy individuals and is highly suggestive of a clonal expansion of a limited set of antigen-specific T lymphocytes.

The natural stimuli that lead to activation of myelin-activated T lymphocytes in MS are as yet poorly understood, but viruses or bacterial superantigens could be responsible for the activation of autoantigen-specific T cells. In addition to the activation of autoantigen-specific T cells, interactions between cell adhesion molecules (CAMs) and selectins expressed on endothelial cells and their ligands on encephalitogenic T lymphocytes could also play an important role in the disease process. By the same token it may be that cytokines released by encephalitogenic T lymphocytes (tumor necrosis factor α (TNF α) and interferon γ) are involved in the upregulation of MHC antigens and adhesion molecules on endothelial cells and antigen-presenting cells (APCs) in the CNS, and the recruitment and activation of other T cells and macrophages. These cytokines can also mediate direct toxicity to the myelin membranes. There is also some evidence supporting a possible role of γ/δ T cells in the secondary inflammatory processes in MS.

Table 1 Myelin antigens

<i>Protein</i>	<i>Size (kDa)</i>	<i>Localization</i>
Myelin basic protein (MBP; 30%)	18.5	Cytoplasm of oligodendroglial cells
Proteolipid protein (PLP)	30	Myelin membrane
Myelin-associated glycoprotein (MAG; 1%)	100	Myelin sheath membrane
Myelin oligodendroglia glycoprotein (MOG)	54	Myelin membrane at the surface of oligodendrocytes

Etiology

The etiology of MS is not known but there is ample evidence that MS has an immunopathogenic basis and that both genetic and environmental factors contribute to the pathogenesis of the disease.

Genetic factors

Most direct evidence to support the influence of genetic factors comes from family studies and from the comparison of concordance in monozygotic (MZ) and dizygotic (DZ) twins. A higher concordance rate (30%) has been found consistently in MZ twins. Furthermore, magnetic resonance imaging (MRI) studies showed lesions in 40% of 'clinically normal' monozygotic twins of individuals with MS. Although the disease is not genetically determined, genetic factors such as the HLA class II alleles within the MHC consistently seem to influence the susceptibility to develop MS. The development of the disorder is believed to be the consequence of multiple genes plus an environmental factor. Different HLA-DR specificities are associated with MS in different ethnic groups and the MHC association with MS appears to be less important than that seen in other autoimmune diseases such as rheumatoid arthritis and type I diabetes, suggesting that other loci contribute to the genetic susceptibility.

Environmental factors

Evidence for environmental factors is largely derived from epidemiological studies. The epidemiological data indicate that MS is related to an infectious agent encountered during childhood. Over the years, more than ten different viruses have been implicated in the etiology of MS, but thus far, no single agent related to the disease has been confirmed. MBP-specific lymphocytes belong to the 'normal' T cell repertoire and it is possible that these cells are expanded by myelin release during MS or virus infection. It is also possible that self-reactive T cells are activated by the recognition of epitopes shared by virus and autoantigen (molecular mimicry).

Diagnosis

Diagnostic criteria have been developed which now have been almost universally adopted and found reliable. Evoked potential studies, MRI and abnormalities of the cerebrospinal fluid (oligoclonal bands and elevated IgG levels) are nonspecific and therefore, by themselves, not diagnostic.

Clinical evaluation

The Expanded Disability Status Scale (EDSS) is the most common clinical scoring system used to evaluate the condition of MS patients. The overall disability score ranges from 0 (normal) to 10 (death due to MS) in half-point increments. The clinical course is quite variable and can be manifested by either relapsing or gradually progressive neurologic deficits. Neuropsychological studies document that 43–65% of MS patients suffer from cognitive dysfunction. Cognitive decline is more frequent at the more advanced stage of the disease and in chronic progressive MS. MRI indicates that considerable subclinical disease occurs and that, early in lesion development, there is a breakdown in the blood–brain barrier.

Magnetic resonance imaging

MRI, a computerized method of depicting the morphology of anatomic structures in cross-section, has been used as one of the parameters to establish the diagnosis of MS and to monitor disease activity. MRI has shown continuous disease activity in clinically stable disease, making it even more difficult to place MS patients in a distinct category.

Therapeutic interventions

Until recently, most attempts to treat MS have focused on general immunosuppressive drugs since the disease was presumed to be immunologically mediated. However, clinical trials were often inconclusive and discouraging. A reliable specific treatment for MS is not yet available. Corticosteroids and corticotropin (ACTH) are commonly used for the treatment of exacerbations and interferon β and copolymer 1 appear to be effective in decreasing the number and severity of relapses. There are, however, many ways of relieving or diminishing the severity of the symptoms of the disease.

More specific treatments have been proposed based on the hypothesis that autoantigen-specific T cells are involved in the pathogenesis of the disease. Studies in EAE have shown that encephalitogenic T cells recognize short peptides of the myelin antigens in the context of MHC molecules, express a restricted number of TCR molecules and secrete interferon γ and tumor necrosis factor α/β (TNF α/β). Although the variability in specificity in the TCR usage in MS has raised questions regarding the relevance of these cells in MS patients, the importance of these cells can be established by abrogating their activity through specific therapies. T Cell vaccination with attenuated MBP-specific T cells in animals and humans has

shown that MBP-specific T cells can be downregulated by an upregulation of anticolonotypic T lymphocytes. Clinical evaluation of a limited number of vaccinated MS patients showed evidence of stabilization of the disease, but awaits further confirmation by means of multicenter clinical trials. Similar experiments with TCR-specific peptides and oral treatment with MBP are promising but also await further evaluation.

MURAMYL DIPEPTIDE

Ichiro Azuma and **Tsuyoshi Otani**, Institute of Immunological Science, Hokkaido University, Sapporo, Japan

Heat-killed mycobacterial cells suspended in mineral oil (so-called Freund's complete adjuvant, FCA) provide one of the most potent immunoadjuvant for the induction of cell-mediated immunity and humoral antibody formation. In 1971, Azuma showed that the cell wall fraction was the major active component for the immunopotentiating activity of mycobacterial cells. The peptidoglycan portion was shown to be the most important for the immunoadjuvant activity of mycobacterial cell wall. In 1974, the minimum essential structure required for the immunoadjuvant activity in the peptidoglycan was defined independently as an *N*-acetylmuramyl-L-alanyl-D-isoglutamine (MDP, muramyl dipeptide; Figure 1) by the groups of E. Lederer and S. Kotani. Several hundred derivatives and related compounds of MDP have been synthesized chemically and their immunopharmacological activities and structure–activity relationships have been investigated (Figure 2). MDP is established as the adjuvant-active component not only of mycobacterial cells but also of other bacterial cell walls.

Figure 1 *N*-Acetylmuramyl-L-alanyl-D-isoglutamine (MDP).

Immunopharmacology and toxicology

MDP has variety of biological activities including:

- adjuvant activity on immune responses including the activation of immune cells, especially macrophages and monocytes,
- induction of cytokines,
- potentiation of nonspecific host resistance against bacterial, fungal and viral infections,
- pyrogenicity,

Figure 2 Adjuvant activity-structure relationship of MDP derivatives. Guinea pigs were immunized with MDP derivatives and antigen (azobenzene arsonate *N*-acetyltyrosine) in water-in-oil emulsion and adjuvant activity was determined by the induction of delayed-type hypersensitivity to antigen (azobenzene arsonate-bovine serum albumin).

- increasing the toxicity of endotoxin (lipopolysaccharide),
- adjuvant arthritogenicity,
- transient leukopenia followed by leukocytosis including monocytosis,
- somnogenic effect and analgesic activity.

These activities suggest that MDP has effects not only on immune responses but also on the neuro-endocrine system. Although extensive data suggests that MDP acts on macrophages/monocytes and induces several cytokines which stimulate immune networks, the MDP receptors on macrophages and other mononuclear cells have not yet been defined.

Pharmacokinetic studies indicate that MDP is rapidly excluded from the blood circulation following intravenous injection of MDP in saline. Within 2 h, 95% of the injected dose of MDP can be recovered unaltered in the urine. Several approaches have been utilized including to obtain more useful long-acting immunopotentiating agents for clinical application, the development of delivery systems such as liposomes and the chemical synthesis of lipophilic MDP derivatives.

Immunopharmacological activities and clinical development of MDP derivatives

The discovery of MDP led to immunopharmacological studies aimed at clinical application of MDP as a chemically defined, fully active immunoadjuvant. These expectations were soon frustrated by the realization that MDP itself is not suitable for clinical use, mainly because of its toxicity and poor pharmacokinetic profile, i.e. the rapid clearance of MDP from the body. This was, however, the beginning of a search for molecules with desirable properties without serious side-effects. Several hundred derivatives were synthesized in order to clarify the interrelationships between structure, activity and toxicity. In 1991, 17 years after the discovery of MDP, romur-

tide (MDP-Lys(L18)) (Figure 3), a lipophilic MDP derivative, was licensed in Japan and employed to induce bone marrow recovery in cancer patients. Following romurtide, other MDP derivatives and analogs, such as MDP (Thr), B30-MDP, MTP-PE and murabutide (Figure 3), are in clinical trials for infectious diseases and cancer.

Immunopharmacological activities of lipophilic MDP derivatives

The lipophilic derivatives show enhanced interaction with macrophages and improved pharmacokinetics, and thus exhibit higher biological activities than MDP. Four such derivatives, MDP-Lys(L18) (romurtide), B30-MDP, MTP-PE and murabutide, have been studied extensively for their immunopotentiating effects and toxicity. Romurtide is effective against experimental infections not only when injected before challenge (immunoprophylaxis), but also when injected simultaneously with or after challenge (immunotherapy). One of the underlying mechanisms of the stimulating effect of romurtide on host resistance is an extremely strong hematopoietic activity for granulocytes and monocytes. Romurtide became the first clinically licensed MDP derivative employed to induce bone marrow recovery following radiation therapy in cancer patients. In patients treated with romurtide, the duration of granulocytopenia is shortened and the number of episodes of infection reduced, allowing completion of cancer therapy. Additionally, romurtide augments platelet production. This effect is of importance because thrombocytopenia caused by cancer chemotherapy is one of the most serious concerns in the management of cancer patients. Clinical trials investigate therapeutic efficacy of romurtide on certain refractory infections, including atypical mycobacterial infection and tuberculosis with multidrug-resistant pathogens, are under progress.

In contrast, B30-MDP is a derivative that exhibits

Figure 3 Chemical structures of various MDP derivatives applied to clinical trials.

adjuvanticity but shows no substantial activity regarding nonspecific resistance to infection. Clinical trials using B30-MDP as an adjuvant effect in an influenza virus vaccine demonstrate that it is able to induce both humoral and cellular immunity. MTP-PE has been shown to be highly effective in generating tumoricidal properties of macrophages. Liposome-encapsulated MTP-PE (L-MTP-PE) has been

designed for *in vivo* targeting to macrophages and decreasing side-effects, and is in clinical trials for cancer. A series of derivatives replacing the D-isoglutaminyl residue with D-glutamine alkyl esters of various sizes was shown to be active but much less pyrogenic than MDP. The representative derivative of this series is murabutide, a compound which does not elicit any febrile response in animal experiments.

Clinical trials of murabutide as a vaccine adjuvant and as a potentiator of nonspecific resistance to infection are currently in progress.

Allison and coworkers found that a MDP analog, *N*-acetylmuramyl-L-threonyl-D-isoglutamine (MDP (Thr)) retained potent adjuvant activity but was less pyrogenic in rabbits and rats. MDP(Thr) has been applied as an immunoadjuvant with the vehicle 'Syn-tex Adjuvant Formulation, SAF', which consists of pleuronic L121, squalane, Tween 80 and PBS.

MDP derivatives as a multicytokine inducer

Differences have been observed in the immunopotentiating activity of each MDP derivative. This may be attributable to the difference in spectrum and/or amount of cytokines induced by each derivative. For example, romurtide has been found to induce stem cell factor (SCF), erythropoietin, granulocyte-macrophage colony-stimulating factor (GM-CSF), macrophage CSF (M-CSF), granulocyte CSF (G-CSF), interleukin 1 (IL-1), IL-6, IL-8, tumor necrosis factor α (TNF α) and interferon γ (IFN γ). For stimulation of hematopoiesis by romurtide, SCF, GM-CSF, M-CSF, G-CSF, IL-1 and IL-8 may be involved in monocyte and granulocyte production and their recruitment to the periphery. SCF, GM-CSF and IL-6 and erythropoietin, may be involved as megakaryocyte CSF and megakaryocyte potentiator, respectively, in platelet production. For the stimulation of nonspecific resistance to infection by the derivative, TNF α and IFN γ may play an important role in addition to other cytokines. In the case of L-MTP-PE, human monocytes/macrophages that phagocytose L-MTP-PE produce IL-1, IL-6, IL-8, TNF α and monocyte chemotactic and activating factor (MCAF). Following intravenous infusion of L-MTP-PE into cancer patients, induction of circulating TNF α , IL-6, and neopterin was demonstrated. The major source of cytokines induced by MDP derivatives is thought to be monocytes/macrophages. Although the receptors for MDP have not been defined, the direct interaction of MDP and romurtide with macrophages has been reported. It is noteworthy that an intracellular receptor for MDP has been suggested, which would explain the stimulating effect on macrophage functions of liposome-encapsulated MDP phagocytosed by macrophages. Lymphocytes may be involved as a secondary source of cytokines, following MDP-induced cytokines secretion by macrophages. For example, murine T lymphocytes produce CSFs when cocultured with macrophages stimulated by romurtide: such macrophages can be substituted by exogenous IL-1.

Clinical toxicology of MDP derivatives

No serious adverse effect of romurtide has been reported since its clinical application with the standard regimen of subcutaneous injection of 200 μ g once a day for 10 days. In phase II and III clinical studies, 704 cancer patients were enrolled to analyze the effectiveness and safety of romurtide. Side-effects caused by romurtide administration were observed in 275 patients (39.1%), mostly fever and a transient skin reaction at the injection site. Other signs and symptoms in 3.6% included skin rash, loss of appetite and nausea. The febrile responses could be controlled by antipyretics without intervention on its effectiveness. In phase II clinical trials of L-MTP-PE for osteosarcoma, the recommended dose was 6 mg m⁻². Despite such a high dose, the side-effects were moderate, including chills (80% of the patients), fever (70%), malaise (60%) and nausea (55%), and 24 week therapy was accomplished. It seems likely that the serious side-effects observed in animals, such as arthritis in rats, uveitis in rabbits and necrosis at the injection site in guinea pigs, are strictly species dependent and humans may not be a high responder to the potency of MDP and its derivatives for inducing such reactions.

Future prospects

Romurtide and other MDP derivatives such as B30-MDP MTP-PE and SAF including MDP(Thr), have been shown to stimulate circulating antibody formation to several viral and malaria vaccines. Romurtide and other MDP derivatives have been reported to enhance host resistance to microbial infections via stimulation of mucosal immune systems after intranasal, oral or intrarectal administration. Romurtide and other MDP derivatives have also been shown to prevent cancer metastasis in experimental models.

The cytokine-inducing properties of MDP derivatives may have an important role to play in cancer therapeutics, especially as a supporting therapy for patients treated with chemotherapy and/or radiation therapy. This approach is expected to improve the quality of life of such patients.

MYCOBACTERIA, INFECTION AND IMMUNITY

Graham A W Rook, Department of Bacteriology, UCL Medical School, Windeyer Building, London, UK

Mycobacteria is a genus of numerous, mostly saprophytic species, many of which have not yet been characterized. They can be divided into two distinct subgenera: the fast growers and the slow growers. *Mycobacteria* differ in structure from other bacteria in that the peptidoglycan layer, present in all bacteria, is covalently linked to a layer of arabinogalactan, which is in turn linked to an outer layer of mycolic acids. These are waxy substances, 60–90 carbon atoms long. Further high molecular weight lipids and glycolipids are noncovalently associated with this outer layer. This structure is resistant to mammalian enzyme systems. Several of its components have striking immunostimulatory properties and *mycobacteria* are routinely included in Freund's complete adjuvant.

The pathogenic mycobacteria

Most *mycobacteria* are environmental saprophytes but the two major pathogenic species, *M. tuberculosis* and *M. leprae*, are amongst the most important pathogens of humans. There are 8–10 million new cases of tuberculosis in the world each year, of which about 3 million die, and this figure is growing with the increased incidence of human immunodeficiency virus (HIV) infection. Similarly, there are between 10 and 15 million cases of leprosy. The major pathogens in the slow-growing subgenus are *M. tuberculosis* (and the related organisms *M. africanum*, *M. bovis* and *M. microti*, which infects rodents), *M. avium* (and the related *M. lepraemurium* which causes a leprosy-like disease in rodents, and *M. paratuberculosis* which infects the

bowels of cattle), *M. intracellulare*, *M. scrofulaceum*, *M. kansasii* and *M. ulcerans* (the cause of Buruli ulcer). Several members of the fast-growing subgenus can cause infections but these are usually opportunistic or abscesses. Relevant species include *M. chelonae* and *M. fortuitum*.

The relevance of environmental mycobacteria

Saprophytic *mycobacteria* are extraordinarily common in the environment, and can be detected in soil samples or scrapings of waterpipes by direct staining and microscopy. Their persistence in the environment is partly attributable to the massive cell wall structure described above. *Mycobacteria* appear not to be part of the normal commensal microbial flora, but they are ubiquitous, resistant to degradation, and very immunogenic, so skin-test surveys reveal that individuals are sensitized to the species characteristic of their own environment. It is now clear that this is relevant to the variable efficacy (0–80% protection in different trials) of vaccination against mycobacterial diseases with BCG, because preimmunization by environmental saprophytes that prime a T_H1 pattern of response is protective, but experimentally, immunization with such saprophytes using doses and routes that prime a T_H2 cytokine pattern, actually increases susceptibility to the disease. It may be that variable exposure to environmental *mycobacteria* can also predetermine patterns of response to heat shock proteins which have been implicated in immunoregulation and autoimmune disease.

Diagnosis of mycobacterial disease

This relies mainly on clinical assessment, microscopy of stained sputum (tuberculosis) or skin smears (leprosy), and culture of the organisms, except for *M. leprae*, which has not been cultivated. Diagnosis of leprosy and opportunist infections is usually backed up by histological examination of biopsies. The skin test using the soluble components of sonicates ('new tuberculin') can be used to distinguish between infections with the various opportunist species. For tuberculosis, skin test with purified protein derivative (PPD) (derived from a crude culture supernatant of *M. tuberculosis*) can be helpful. The delayed hypersensitivity response to PPD can be positive because of present or past tuberculosis, previous BCG vaccination, or heavy exposure to cross-reactive environmental mycobacteria. Therefore, interpretation of the test depends on the environment from which the patient comes. In past or present cases of tuberculosis, the tuberculin test site is frequently necrotic (discussed in detail below). Serodiagnosis remains unsatisfactory for three reasons. First, these assays do not distinguish easily between past and present infection. Secondly, all individuals are exposed to highly immunogenic cross-reactive antigens from environmental species. Thus antibody levels in tuberculosis patients are often no higher than in normal donors, particularly while the patient is acutely ill, though the titer may rise after treatment. Thirdly, although the problem of cross-reactive environmental species would theoretically be avoided if species-specific epitopes could be discovered, such epitopes are either poorly immunogenic, or immunogenic in only a percentage of individuals. Alternative approaches receiving intensive study include the detection of mycobacterial antigens such as persistent carbohydrates in patients' serum and urine, or the use of the polymerase chain reaction to detect mycobacterial DNA sequences.

Host factors and susceptibility to mycobacterial disease

There are weak associations between mycobacterial disease and major histocompatibility complex (MHC) haplotypes. In leprosy, these seem to determine the type of disease which develops rather than overall susceptibility. In rodents, susceptibility is also linked to the *bcg/Ity/Lsh* gene, which affects aspects of the baseline state of macrophage activation, and may be involved with control or transport of nitric oxide. Susceptibility to *M. tuberculosis* is particularly sensitive to factors that decrease T cell function, such as severe stress leading to activation of the cytokine

hypothalamo-pituitary-adrenal axis, protein malnutrition and immunosuppression. Tuberculosis occurs early during infection with HIV. Infection with the *M. avium/intracellulare/scrofulaceum* (MAIS) complex is seen when greater degrees of T cell dysfunction occur.

The antigens of mycobacteria

The genes for numerous mycobacterial antigens have been cloned and sequenced, and epitopes recognized by T cells and B cells have been identified. This has not led to the definition of 'protective' antigens or epitopes that seem particularly suitable for use in subunit vaccines. The 65 kDa heat shock protein (hsp) and several secreted proteins have been shown to be capable of eliciting protective responses in animal models (mice and guinea pigs), but at present it seems that the important factor is the nature of the response elicited rather than its fine specificity. For instance the 65 kDa hsp is not protective against tuberculosis when given in incomplete Freund's adjuvant, which elicits a major T_H2 component, but it is very protective when administered as macrophages transfected with the hsp65 gene. The transfected cells evoke a T_H1 response and cytotoxic T cells. Other functionally important antigens include the cytokine-triggering glycolipids lipoarabinomannan and trehalose dimycolate (see below).

Tuberculosis

Immunity to *M. tuberculosis*

Immunity to mycobacteria depends upon cell-mediated pathways described below. The critical problem in both leprosy and tuberculosis is that after prolonged treatment with antibacterial drugs, 'persisters' remain which can lead to relapse unless treatment is prolonged. Optimal so-called 'short course' chemotherapy for tuberculosis therefore takes 6 months. In other bacterial infections, it is sufficient to kill the majority of the bacteria with drugs, because the host response rapidly eliminates the remainder. This does not occur in tuberculosis because the host's response is inappropriate and causes tissue damage (immunopathology) rather than effective bacterial killing.

Immunity in the mouse Experiments with neutralizing antibodies to cytokines and with gene knockout mice have shown that immunity requires MHC class II, a T_H1 cytokine pattern, and tumor necrosis factor α (TNF α). This is supported by evidence that when murine peritoneal macrophages are

activated by interferon γ (IFN γ) they develop the ability to inhibit the proliferation of *M. tuberculosis* and *M. avium*, and MHC class II-restricted T cell lines cultured with infected murine macrophages will exert this effect via release of IFN γ . The ability of murine macrophages to inhibit mycobacteria may be related to the ability of these cells to make nitric oxide. IFN γ activates this pathway, whilst TNF α , released in response to several mycobacterial components triggers the production of large amounts of nitric oxide by the IFN γ -activated cell.

Gene knockout has also revealed a requirement for β_2 -microglobulin in immunity to mycobacteria. This may indicate a role for CD8⁺ MHC Class I-restricted cytotoxic T cells, or for the $\alpha\beta$ T cell receptor-bearing CD1-restricted CD4⁺CD8⁻ T cells that have been defined recently. These cells can recognize mycobacterial lipids and glycolipids. Similarly, many of the lymphocytes that bear $\gamma\delta$ T cell receptors recognize mycobacterial antigens, including heat shock proteins, compounds containing 5' triphosphorylated thymidine, and prenyl pyrophosphate derivatives. Nevertheless, these various cell types all secrete IFN γ , and are cytotoxic. They therefore fit within the concept of 'type 1' response. Presumably the cytotoxicity releases bacteria from effete macrophages so that they can be taken up by fresh cells.

In contrast, if a type 2 response is primed, mice become more susceptible to tuberculosis than are nonprimed controls, and in progressive disease the response in mice switches from T_H1-dominated to a mixed T_H1 plus T_H2, or perhaps T_H0, pattern.

Immunity to tuberculosis in humans It is probable that in humans, as in mice, immunity is associated with a T_H1 pattern of response leading to macrophage activation and to cytotoxic removal of effete infected cells. Studies of cells in tuberculosis pleural effusions support this concept, since this is a high resistance form of the disease, and the T_H1 pattern dominates. However data are less complete than in the mouse because there is still no unequivocal proof that human macrophages can kill *M. tuberculosis*. This may change now that protocols able to induce nitric oxide production by human macrophages have been devised.

The immune response in tuberculosis patients Studies of peripheral blood mononuclear cells from tuberculosis patients precultured with mycobacterial antigen *in vitro* reveal both T_H1 and T_H2 cells. If peripheral blood lymphocytes from patients are examined without preculture it becomes apparent that the interleukin 4 (IL-4) gene is expressed, while there is a deficit in IL-2 expression. Similarly tuberculosis patients

have specific immunoglobulin E (IgE) and IgG4 antibody. Both of these are IL-4-dependent in humans. Many patients' sera also contain high levels of IL-10. When tuberculin test sites were studied using a laser Doppler velocimeter it was found that the extent to which blood flow was reduced in the centre of the site at both 6 h and 48 h, was related to the level of specific IgE antibody to *M. tuberculosis*. This appears to represent incipient necrosis. Thus as in mice, progressive disease in humans is associated with the presence of an inappropriate T_H2 component.

The role of TNF α in tuberculosis The alveolar macrophages and monocytes of tuberculosis patients are primed for release of TNF α . The alveolar lavage cells release TNF α apparently spontaneously in large quantities *in vitro*. Circulating free TNF α is rarely detectable in serum, but there are high levels of soluble TNF α receptors. *M. tuberculosis* is itself a potent trigger of cytokine release from primed macrophages. The major triggering molecule in *M. tuberculosis* is a phosphatidylinositol mannoside known as lipoarabinomannan (LAM), but other components such as trehalose dimycolate (cord factor) may also have this property. This cytokine appears to have a dual role in tuberculosis, being needed for protection, but also playing a role in immunopathology. The drug thalidomide, which reduces the half-life of the mRNA encoding TNF α , causes weight gain and symptomatic relief in tuberculosis patients.

The immunopathology of tuberculosis

The lesions are necrotic in tuberculosis patients, and the disease is characterized by fever and weight loss. Moreover, as first described by Koch in tuberculosis guinea pigs (the 'Koch phenomenon'), a tuberculin test in past or present tuberculosis patients evokes a necrotic response. Tuberculin itself is nontoxic, and it does not evoke necrotic skin-test responses in past recipients of BCG or in tuberculoid leprosy patients, even when there is vigorous induration. Therefore necrosis is not an inevitable component of a positive cell-mediated response to mycobacterial antigen, but reflects a particular mechanism, the likely nature of which is described below. It is possible that the necrosis helps to wall off established infectious foci, but it is ineffective in the elimination of persistent bacilli, and fails to prevent relapse if chemotherapy is curtailed.

The mechanism of the tissue damage in tuberculosis The necrosis (Koch phenomenon) may be explained by the recent observation that the toxicity

of TNF α in a mycobacterial lesion depends upon the nature of the T cell response involved. Thus although TNF α fails to cause necrosis if injected into T_H1-mediated inflammatory sites, it provokes striking tissue damage when injected into sites mediated by T cells with a mixed T_H1/T_H2 cytokine profile. This can be shown in deliberately immunized mice, primed so that they have T_H1 or mixed T_H1/T_H2 responses to mycobacterial antigen, or it can be shown in tuberculosis mice in which injected TNF α becomes tissue-damaging once the response has shifted from T_H1 to mixed T_H1/T_H2, as occurs in the progressive phase of the disease.

Immunotherapy of tuberculosis

Conventional treatment relies on antibiotics and chemotherapeutic agents, and must be continued for at least 6 months for the reasons explained above. However, recent clinical trials suggest that the tissue-damaging pattern of response to *M. tuberculosis* outlined above is potentially subject to immunoregulatory restraints which can be activated by an intradermal injection of autoclaved *M. vaccae*. This is thought to operate by restoring a T_H1 pattern of response to shared epitopes such as those of heat shock proteins.

Leprosy

The spectrum of leprosy

M. leprae cannot yet be cultivated *in vitro*. It will infect primates and armadillos, and give limited proliferation in mice after infection with small numbers of organisms. It enters numerous different cell types *in vivo*, and is found inside Schwann cells, neurons, endothelial cells, muscles and fibroblasts. It proliferates within the cytoplasm, rather than within phagosomes, and this may shield it from protective pathways. It is the predilection for nerves that is responsible for most of the pathology.

Leprosy patients can be classified on a 'spectrum' according to the apparent efficacy of the cell-mediated response. The problems that require explanation are quite different at the two extremes of this spectrum.

Tuberculoid leprosy In tuberculoid disease, the *in vivo* and *in vitro* correlates of T cell-mediated responsiveness, such as skin-test responsiveness and lymphoproliferation in response to antigens of *M. leprae*, appear to be intact, bacilli are few and histologically the lesions are classical T lymphocyte-dependent granulomata containing CD4⁺ T cells, activated macrophages, and epithelioid cells, with a

few CD8⁺ cells round the periphery. The lesions are largely due to nerve damage secondary to expansion of the granulomata and inflammation within nerve sheaths. There is evidence of T_H1 cytokine production in these lesions. Without treatment, many of these individuals will downgrade towards the lepromatous pole, where the T_H1 response is compromised (see below). Since the T cell-mediated responses appear to be functioning, it is not clear why this type of leprosy frequently fails to be self-limiting.

Theoretically, two types of explanation seem possible. First, the T cells responding may be the wrong type. This cannot be resolved at present because we do not know what effector mechanisms are required for the elimination of *M. leprae*, though as for tuberculosis, immunity is likely to depend upon macrophage activation and cytotoxic T cells mobilized by a T_H1 response. There is a T_H1 response in tuberculoid leprosy so why do the patients have a disease?

An alternative hypothesis is that the response in tuberculoid patients is adequate in mechanism, but is directed towards the wrong antigens. Again this cannot be resolved until protective antigens can be identified, but one possibility is that the critical antigens are the secreted ones. These would presumably be the first to be available for presentation to T cells, and would therefore allow a rapid response to infection. They would also allow recognition of live organisms. Thus it is possible that tuberculoid leprosy patients have a chronic granulomatous response to persistent cell wall fragments derived from dead organisms which are difficult to metabolize, while their lymphocytes fail to recognize the live organisms proliferating elsewhere.

Lepromatous leprosy In contrast, lepromatous patients show minimal evidence of T cell-mediated immunity either *in vivo* or *in vitro*, and their lesions consist of large numbers of macrophages filled with bacilli, showing no signs of activation. Often these patients remain unresponsive to the organisms even after years of treatment when the antigen load has been drastically reduced. Thus in this form of leprosy we need to explain the persistent absence of a response, whereas in tuberculoid leprosy the problem is the paradoxical failure of a superficially intact one. The meaningful study of this type of leprosy is hampered by the fact that the organism is nontoxic, and in the absence of a strong inflammatory response it can proliferate within the patient's tissues for many years before its presence becomes apparent. Thus much of what has been revealed by immunologists may be the consequence of prolonged heavy antigen

load, rather than the actual basis for the failure to eliminate the organisms in the first place. It is now clear that the lack of an apparent T cell-mediated response to *M. leprae* in lepromatous leprosy is not due to a lack of T cells recognizing this organism. However the T cells present tend to express T_H2 cytokines. Moreover peripheral blood leukocytes from some (but not all) patients give a proliferative response to *M. leprae* if the cultures are supplemented with IL-2 or other lymphokines.

Several groups have been able to demonstrate T cells that suppress lymphoproliferation in the presence of *M. leprae*. These may represent some type of 'suppressor' cell, or the effects seen may be attributable to T_H2 cytokine production. It remains possible that these phenomena are secondary to the presence of a large antigen load for many years before diagnosis. It may be significant that once the organism has become established within nerves (which do not have lymphatics) and endothelial cells, antigens will be released directly into the circulation which is likely to evoke suppression of cell-mediated responses, and high antibody levels.

Links between mycobacteria and autoimmunity

There are several aspects of the mycobacteria which lead to the possibility that these organisms, or antigens cross-reactive with them, are involved in autoimmune disease.

1. Tuberculosis is one of a group of diseases in which there is a rise in the percentage of circulating IgG molecules that lack terminal galactose from the oligosaccharide which is always present on the CH₂ domain of the Fc. This 'glycoform' of IgG is known as agalactosyl IgG. There is also a transient rise during episodes of erythema nodosum leprosum (ENL) in leprosy. The other conditions where agalactosyl IgG rises strikingly are Crohn's disease, rheumatoid arthritis and rodent models of autoimmune arthritis.
2. The mycobacterial 65 kDa heat shock protein (or autoantigens cross-reactive with it) is implicated in the pathogenesis of the rodent models of arthritis, and of the human disease.
3. Induction of arthritis in the rodent models can be blocked by pretreatment with the mycobacterial 65 kDa hsp.

In view of the fact that mycobacteria are ubiquitous in soil and water, but absent from the commensal microbial flora, there is the tantalizing possibility that variable exposure to mycobacteria in different geographical environments plays a role in the regulation of susceptibility to certain autoimmune diseases.

MYCOPLASMA, INFECTION AND IMMUNITY

Juliane Hentschel, Department of Neonatology, Virchow-Klinikum, Humboldt-Universität Berlin, Berlin, Germany

Mycoplasmas and ureaplasmas are bacteria of the class Mollicutes (soft-skinned), the order Mycoplasmatales and the family Mycoplasmataceae. They have no cell wall, the cytoplasm being bordered by a membrane only, and their morphology is varied, from filamentous to flask-shaped, and in older cultures coccoid (Figure 1). They are considered to be

among the smallest self-replicating organisms; in fact they are so small and pliable that they can pass through bacterial filters. In the history of mycoplasmaology this has caused confusion, and the first described mycoplasma, the agent of bovine pleuropneumonia, was mistaken for a virus. Later, because of the absence of a cell wall, mycoplasmas were considered to be L-form bacteria and only in the early 1960s, based on determinations of the guanine–cytosine content and on DNA–DNA hybridization data, were they recognized as a class of their own.

Except for *M. penetrans* which is an intracellular organism, mycoplasmas and ureaplasmas colonize cell surfaces, usually those of epithelial cells of the upper respiratory and urogenital tracts. In the human they are mostly harmless commensals. However, mycoplasmas can also cause serious disease in humans and animals, from farmed crocodiles to poultry and cattle. Other mollicutes can infect insects and plants. Moreover, mycoplasmas are contaminants of about 30–50% of cultured animal cell lines.

Characteristics of the organism

The genome sizes of mycoplasmas range from 580–1380 kilobase pairs. Characteristic for mycoplasma DNA is its low guanine plus cytosine content. The genomes of two species, *M. genitalium* and *M. pneumoniae*, were recently completely sequenced. Because of their parasitic growth in a nutrient-rich environment, mycoplasmas can survive without the enzymatic equipment to synthesize vitamins, amino acids, fatty acids, cholesterol and nucleotides. This implies that cultivation of mycoplasmas requires rich media with appropriate additions of these precursors for macromolecules and lipids. It also means that mycoplasmas are notoriously fastidious and especially difficult to cultivate from clinical specimens.

Host–pathogen interactions

In order to survive in the host, mycoplasmas have to adhere to the host tissue, mostly the epithelium, to have access to the appropriate nutrients, and to avoid the defense system. Studies of mycoplasma–host cell adhesion have centered around *M. pneumoniae* and *M. genitalium*. Both organisms

Figure 1 Scanning electron micrograph of critical point-dried mycoplasmas from a liquid culture. (A) *M. pneumoniae*; (B) *M. fermentans*; (C) *M. hyorhinis*. Bars represent 1 μ m (Courtesy of M Rohde, Gesellschaft für Biotechnologische Forschung mbH.)

are of a characteristic flask-shape, with several proteins, so-called adhesins, which are involved in the adhesion process, clustered at specific tip organelles. These proteins have been identified in studies involving trypsin treatments, specific antibodies, and mutants and revertants which lost and regained the ability to cytoadhere. The cellular receptor molecules for *M. pneumoniae* adhesins were identified as long-chain sialo-oligosaccharides of the Ii antigen type. This may contribute to the fact that high-titer cold agglutinin-type autoantibodies against this antigen are occasionally found after *M. pneumoniae* infections. According to findings in a mouse model, colonization of epithelia is related to hormonal status: estradiol promotes attachment to cervical and uterine epithelia, possibly by receptor induction.

As shown in animal models of mycoplasma infections, phagocytes which amass in infected tissue comprise the first line of defense against these organisms. However, in the absence of specific antibodies, mycoplasmas can survive neutrophil phagocytosis. This may be one of the mechanisms by which dissemination into unusual sites and persistence occurs in hypogammaglobulinemic patients. Interestingly, *in vitro* mycoplasmas can modulate class II major histocompatibility complex (MHC) expression by macrophages. Whether this influences the antigen-presenting function of these cells during an actual infection is still unclear. The fact that patients with hypogammaglobulinemia are more frequently colonized with mycoplasmas and ureaplasmas than persons with an intact immune system, and the finding that a significant fraction of those patients also suffer from mycoplasmal septic arthritis strongly suggest that antibodies protect the host from these bacteria. Secretory immunoglobulin A (IgA) appears to be important in preventing localized colonization, whereas systemic antibodies may protect from primary infection and secondary spread from localized colonization. Unlike other mycoplasma species, *U. urealyticum* possesses a host-specific IgA protease as a potential virulence factor. Moreover, ureaplasmas and many mycoplasmas, e.g. *M. fermentans*, *M. hominis*, *M. hyorhinis* and several others, have the facility to escape the humoral immune response by undergoing high-frequency antigenic variation of some of their surface antigens. The genetic mechanisms for this 'phase variation' were recently elucidated. There have been surprisingly few recent investigations into the involvement of T cells in a specific response to mycoplasmas, although early studies had shown that patients develop specifically proliferating T cells a few weeks after *M. pneumoniae* infection, and that this response may persist for several years. The importance of cellular immunity also became

evident from studies in an animal model with nude mice. These animals, which are devoid of a functional T cell repertoire, could not be protected, as control animals, against vaginal colonization by *M. pulmonis* by prior oropharyngeal infection with the same organism.

In vitro effects of mycoplasmas and their products on various cells of the immune system are manifold. Occasionally an apparently mycoplasma-mediated inhibition of lymphocyte proliferation was recorded in experiments in which proliferation was measured by uptake of radioactive thymidine. However, this effect was found to be due to scavenging of thymidine by living mycoplasmas. On the other hand, stimulation of B or T cell proliferation by heat-killed mycoplasmas has been noted, as well as mycoplasma-mediated generation of cytotoxic T cells, and activation of macrophages to become cytolytic and to release proinflammatory cytokines, nitric oxide and arachidonate metabolites. Some of the effects on lymphocytes are indirect, and are due to a macrophage activator that is present to various extents in the membranes of many if not all mycoplasmas and ureaplasmas. This macrophage activator also modulates class II MHC expression. Recent biochemical data indicate that this material consists of mycoplasmal lipoproteins and lipopeptides derived from the former. *M. arthritidis*, a strain arthritogenic in mice and rats, is the only mycoplasma known so far which produces a superantigen. This protein was recently sequenced, and has been the subject of many studies that have elucidated its specific interaction with particular T cell receptor and class II MHC species.

Mycoplasmas and ureaplasmas in human disease

This section focuses on the role of mollicutes in the human. While most mycoplasma species are harmless commensals in the human and, where pathogenic, are life-threatening only under exceptional circumstances, one should be aware of the fact that some mycoplasmas exist in animals that cause 100% morbidity and 50% mortality, as e.g. *M. mycoides* subspecies *mycoides*, the agent of pleuropneumonia in cattle.

As with other bacteria, mycoplasmas may be considered normal flora in one site, e.g. *Ureaplasma* colonizing the human vagina, and abnormal when present at other sites, e.g. when found in joint fluid. Such findings may, in fact, be a first sign of immunosuppression in hypogammaglobulinemia. The induction of chronic disease states in patients with normal defense systems is an intriguing feature of mycoplasma infections. Besides the above-mentioned

evasive strategies which are common to most mycoplasmas, each pathogenic mycoplasma may present specialized mechanisms of evasion of the immune system.

Primarily respiratory pathogens

Although *M. pneumoniae* resides primarily in the oropharynx and can be isolated from secretions during lower respiratory disease, this organism has occasionally been found in the urethra or cervix of patients attending clinics for sexually transmitted diseases. Aside from causing classical 'atypical pneumonia' in school-age children, younger age groups may exhibit bronchitis, bronchiolitis, pharyngitis and croup. *M. pneumoniae* and concomitant host reactions can induce hemolytic anemia, Stevens-Johnson syndrome, myo- and pericarditis (9% of cases) and adult respiratory distress syndrome. *M. pneumoniae*-associated neurologic diseases (encephalitis, meningitis, myelitis, polyradiculitis) are being recognized with increasing frequency (following at least 1/1000 respiratory infections), some with debilitating or fatal outcome. Direct invasion, a neurotoxin, autoimmune complex formation with gangliosides or vasculopathy are all being discussed as pathomechanisms. Neuropathy, including Guillain-Barré syndrome following *M. pneumoniae* infection, has been associated with the induction of autoantibodies to galactocerebroside.

Primarily urogenital pathogens

U. urealyticum was first isolated from male patients with nongonococcal urethritis (50% of cases). It sometimes causes prostatitis, but may otherwise be found in the male urethra without any symptoms. *U. urealyticum* is normal flora of the female genital tract after onset of sexual activity (in some populations up to 80% of pregnant women are positive), but in conjunction with anaerobic gram-negative rods, *Gardnerella vaginalis* and a concomitant depression of protective lactobacilli, it is part of the pathologic bacterial vaginosis and is then present in large numbers. Bacterial vaginosis predisposes to upper genital tract infections (especially endometritis) and an adverse pregnancy outcome, and it doubles the risk of spontaneous preterm delivery. Like other organisms associated with bacterial vaginosis, *U. urealyticum* and *M. hominis* are suspected to be involved in intrauterine growth retardation of the fetus. Isolation of *U. urealyticum* from the chorioamnion with signs of histological chorioamnionitis rather than colonization of the lower genital tract is associated with prematurity and low birthweight. Mid-pregnancy antimicrobial treatment directed against anaerobes and *U. urealyticum*

reduces the rate of premature delivery in high-risk women with bacterial vaginosis.

The prevalence of *U. urealyticum* depends on the population studied. In Europe, about one-tenth of mature newborns carry *U. urealyticum* at birth, whereas one-third of extremely low birthweight infants (prematures of less than 1000 g birthweight) are colonized. In mature newborns, congenital *Ureaplasma* pneumonia has occasionally been described. Extremely low birthweight infants with *Ureaplasma* colonization of the lower respiratory tract, however, have a twofold increase in chronic lung disease characterized by the prolonged need for ventilation and/or supplemental oxygen.

M. hominis can be found in male urethritis in 19% of cases, and in the female genital tract as a commensal and as a member of the bacterial vaginosis family. Pelvic inflammatory disease, pyelonephritis, postpartum fever, posthysterectomy wound infection and fetal scalp abscesses may ensue from there. *M. hominis* has also been isolated from respiratory secretions of premature infants with pneumonia and in adult pharyngitis. In patients with reduced immunity, dissemination of genital mycoplasmas to other sites is possible, e.g. to the cerebrospinal fluid in premature infants, to the joints of hypogammaglobulinemic persons or nosocomially to operative wounds. *M. hominis* and *U. urealyticum* have recently been demonstrated in adenotonsillitis in children.

M. genitalium has been found associated with male urethritis (in 14–17% of cases), female urethritis, salpingitis, pelvic inflammatory disease, and arthritis in the immunocompromised state. *M. genitalium* has also been detected in the respiratory tract, but care must be taken in distinguishing this organism from *M. pneumoniae*, as both behave similarly in culture and share genetic and antigenic traits.

Mycoplasmas/ureaplasmas and arthritis

Association of mycoplasmas or ureaplasmas with arthritis in animals is an accepted fact and has been thoroughly studied in animal models such as, e.g. that with *M. arthritidis* in the mouse and rat. Although *M. arthritidis* may be a special case, as this strain which does not typically infect humans produces a superantigen, an association of mollicutes with human arthritis has long been under debate, and solid evidence in favor of an involvement of mycoplasmas and ureaplasmas in arthritis is increasing. In general, these organisms remain undiscovered unless specifically sought. Thus, mollicutes are taken to be a rare cause of septic inflammatory arthritides. However, mollicutes are responsible for about 40%

Table 1 Antibiotic susceptibilities of mycoplasmas causing human disease

	Antibiotic minimal inhibitory concentration (MIC) ($\mu\text{g ml}^{-1}$)		
	<i>M. pneumoniae</i>	<i>M. hominis</i>	<i>U. urealyticum</i>
Tetracycline	0.06–1	0.06–128 ^a	0.5–256 ^a
Doxycycline	0.25–0.5	0.03–16	0.06–256 ^a
Erythromycin	≤ 0.06 –8	R	0.25–>128
Clarithromycin	≤ 0.04 –0.125	R	0.03–0.5
Roxithromycin, azithromycin	<0.01–0.03	R	0.5–4
Chloramphenicol	1.6–6.4	<0.2–0.8	0.4–16
Ciprofloxacin	0.5–8	0.25–8	2–16
Clindamycin	0.5–4	0.03–2	1–>128

R, resistant. The large spread in MIC is due to the Tet M determinant in some strains, causing high-level tetracycline resistance. Wherever a wide range is given, susceptibility testing is recommended.

of the septic arthritides in patients with hypogammaglobulinemia or other immune deficiencies. *M. hominis*, *M. genitalium*, *M. fermentans* and *U. urealyticum* have all been isolated from the joint fluid of such patients. Diagnosis of mollicutes is tedious and time-consuming when done by culture but will eventually become easier and more sensitive using the polymerase chain reaction (PCR). This may be the reason why mycoplasmas only recently were also detected in the joint fluid of immunologically normal patients with different forms of inflammatory rheumatic diseases but not in control persons.

In the case of reactive arthritis, defined as a seronegative oligoarthritis triggered by a preceding extra-articular infection, involvement of mollicutes is also likely. However, since the urogenital tract of a great percentage of sexually active persons is colonized with mollicutes without causing any symptoms, the establishment of a causal relationship between colonization with mollicutes and a reactive arthritis has to rely on statistics. These are in favor of such a correlation but may need confirmation.

Mycoplasmas and HIV

At about the same time as the first effects of mycoplasmas on human immunodeficiency virus (HIV) replication in cell culture were reported, a discussion about the role of mycoplasmas as cofactors in the acquired immune deficiency syndrome (AIDS) was started, and it continues today. While a seeming inhibition of reverse transcriptase by mycoplasmas was found to be due to mycoplasmal nuclease, and stimulation of virus replication in some *in vitro* systems could be explained by proinflammatory cytokines, involvement of mycoplasmas in the progress of HIV-mediated disease is still under debate. Depending on the methodology used, various or no mycoplasma species were found associated with HIV infection.

Several independent studies agree on the association of *M. penetrans*, a strain which is transmitted by homosexual practices, with HIV. The situation with *M. fermentans* is less clear: some studies report an association of this mycoplasma with HIV, whereas others find no such correlation.

Diagnosis

Routine diagnosis is limited to the relatively few mollicutes involved in human disease. Mycoplasmas can be diagnosed 1) indirectly by testing patient's sera for specific antibodies, 2) directly by cultivation and identification, and 3) by methods of molecular biology. Ureaplasmas are usually not diagnosed by serological means but by cultivation or PCR. Sero-diagnosis (IgM and IgG) can be achieved by complement fixation assays or enzyme-linked immunosorbent assays. For *M. pneumoniae* a commercial glycolipid antigen preparation is available which is suitable for a preliminary diagnosis only, as this antigen is not entirely specific. Metabolic inhibition tests or (hem)agglutination assays are now less frequently in use. Cold agglutinins, though not specific, may be an indication of an *M. pneumoniae* infection. Successful cultivation and isolation requires careful collection of samples from the appropriate sites, short transportation times or preservation, and the use of different formulations of broth and agar media in a specialized laboratory. All these parameters are critical, and cultivation may require 2 weeks or longer. A great number of poly- and monoclonal antibodies specific for several mycoplasma species or different serovars of *U. urealyticum* are available. These serve in the identification of individual colonies on agar blots or in western blot analysis. Also DNA restriction or protein separation patterns may help to identify less frequently occurring species. As myco-

plasmas quickly become nonviable during transport of clinical material and in body fluids containing antibiotic substances, strain-specific DNA probes for *in situ* detection and PCR have been developed for all pathogenic mycoplasmas. The sensitivity and specificity of PCR comes close to or surpasses that of cultivation methods. For all that, culture confirmation may be essential because PCR is notorious for possible false-positivity, and antimicrobial sensitivity testing and future reference cultures may be needed for clinical purposes. However, used judiciously, molecular tools will certainly change epidemiological data on mycoplasmas, as the true incidence and prevalence of these organisms becomes apparent.

Treatment

Many mycoplasma infections do not require treatment. Vaccines against pathogenic mycoplasmas of humans are presently not available, a major difficulty being the antigenic variability of most mycoplasmas. For animal mycoplasmal diseases, inactivated and live vaccines have been developed against bovine, porcine, avian and caprine pneumonia.

Since mycoplasmas lack a cell wall, they are not susceptible to antibiotics such as β -lactams which inhibit cell wall synthesis. Aminoglycosides are merely inhibitory. Treatment options with *in vitro* patterns of resistance (minimal inhibitory concentrations) are listed in Table 1. Among other caveats, care must be taken to adapt antibiotic therapies to age (e.g. tetracyclines are toxic for the fetus and infants), to the causative organism (e.g. *M. hominis* is universally resistant to erythromycin) and to the site of infection (e.g. erythromycin penetrates inadequately into body fluid spaces).

MYELOID ANTIGENS

David C. Linch, Department of Haematology, University College London Medical School, London, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Hematopoietic cells express a range of antigens, which in some cases are restricted to a particular myeloid lineage or stage of differentiation. The International Workshops and Conferences on Human Leukocyte Differentiation Antigens, have classified, a number of antigens as myeloid antigens (Table 1). This is a somewhat arbitrary distinction and signifies lack of reactivity of the antibodies in that particular cluster of differentiation (CD) with the mature lymphoid elements of the blood as much as myeloid specificity. Antibodies reactive with the myeloid CD13 antigen for instance, also react with the connective tissue of lymph nodes, thymus and spleen, bile canaliculi and sinus lining cells in the liver, glomeruli and proximal tubules in the kidney, and some skin cells, pancreatic cells, and cerebellar perineural cells. One of the most myeloid-specific antigens appears to be CD66b, which is a member of the carcinoembryonic antigen family.

Differentiation-associated expression of myeloid antigens

The changing expression of some of the myeloid antigens during granulocytic and monocytic differentiation is illustrated in Figure 1. Use of antibodies reactive with these antigens has assisted in the identification and purification of cell populations at specific stages of differentiation. Primitive myeloid cells express the CD34 antigen as do the primitive lymphoid progenitor cells. Successful hematopoietic stem cell transplants can be carried out, using purified CD34⁺ bone marrow or mobilized peripheral blood cells, although it has been suggested recently that a small population of the most primitive stem cells are CD34 negative. Considerable attention has been focused on the phenotypic and functional subdivision of the CD34⁺ hematopoietic cells. The more primitive stem cells, that give rise to long-term bone marrow cultures, are CD33⁻, CD38⁻, CD45RA^{-/low}, CD71^{-/low}, *c-kit* (SCF receptor CD117)^{low}. There is controversy as to the major histocompatibility complex (MHC) class II status of primitive stem cells. In fetal marrow those cells with the highest plating and replating efficiency are CD34⁺, CD38⁻, HLA-DR⁺, whereas in adult marrow those cells capable of giving rise to long-term cultures are HLA-DR⁻. The vast majority of colony-forming cells are HLA-DR⁺, but the expression of this antigen then ceases between

the myeloblast and promyelocyte stage. The CD13 antigen is expressed on a proportion of progenitor cells, and is most strongly expressed on those cells which are actively cycling. Antibodies to the CD33 and CD13 antigens have proved valuable in the diagnosis of myeloid leukemias.

A number of antigens appear in the identifiable granulocytic and monocytic precursor pool including CD14 and CD15. CD14 was initially thought to be monocyte specific but is expressed weakly on at least a proportion of granulocytes. CD15 is expressed on all neutrophils, most monocyte precursor cells, but only a small proportion of circulating monocytes. Of particular interest is the CD10 antigen (CALLA), originally thought to be restricted within the hematopoietic system to early B lymphoid cells and now known to be expressed as a late event in neutrophil differentiation and also to be present on bone marrow stromal cells.

The phenotype of eosinophils and basophils has some similarities with neutrophils but there are also distinct differences. Both eosinophils and basophils express the leukocyte integrins (CD11a, CD11b, CD11c, CD18), CD13, CD32, (FcγRII), CD35, CD43, CD44, and CD45, as do neutrophils. In contrast to neutrophils, eosinophils express CD9 and lack CD10, CD16 (FcγRIII) and CDw17. Basophils, unlike neutrophils, express CD25 (IL-2R), CD38, CD40 and CD54 (ICAM-1), but lack CD10, CD16 (FcγRIII), CDw65, CD66a and CD66b. CD15 expression is weak.

The phenotype of early erythroid progenitor cells is similar to that of early granulocytic and monocytic progenitor cells, although expression of the transferrin receptor (CD71) may be higher on the erythroid cells. With erythroid differentiation into the recognizable precursor pool, there is acquisition of a large number of red cell-specific antigens, including many blood group antigens, 'band III' and glycoporphin. Similarly, megakaryocytes and platelets acquire a number of differentiation-associated antigens, such as gpIIb (CD41), gpIX (CD42a), gpIbα (CD42b), gpIbβ (CD42c), gpV (CD42d), the vitronectin receptor (CD51), the integrin β₃ subunit (CD61) which can associate with CD41 or CD51, and P-selectin or PADGEM (CD62P). Some platelet lysosomal proteins only become expressed on the cell surface after platelet activation (e.g. CD63, CD107a, CD107b) and antibodies to these antigens are being increasingly used in the assessment of platelet status and function.

Table 1 Selected antigens expressed on myeloid cells

<i>CD no.</i>	<i>Mol. wt (kDa)</i>	<i>Biochemical nature</i>	<i>Reactivity with mature hematopoietic cells</i>	<i>Reactivity with other tissue cells</i>
10	100	Neutral endopeptidase	Neutrophils	Lymphoid progenitor cells. Renal glomeruli and tubular epithelium. Myoepithelial cells of breast and salivary glands. Some smooth muscle cells
13	150	Aminopeptidase N	Monocytes, macrophages, granulocytes	Some myeloid progenitor cells; lymphoid organ connective tissue; renal glomeruli and proximal tubules; bile canaliculi; liver sinus lining cells; cerebellar perineural cells around skin sweat glands; pancreatic ducts and secretory cells
11a	180 α chain	α/β Heterodimeric glycoprotein (integrin family)	All leukocytes	Neuroectodermal cells
11b	165 α chain	α/β Heterodimeric glycoprotein (integrin family) CR3	Granulocytes, monocytes, NK cells	
11c	150 α chain	α/β Heterodimeric glycoprotein CR4	Monocytes, granulocytes, NK cells, some T cells, some B cells	
18	95 β chain	α/β Heterodimeric glycoprotein; CD18 is linked to CD11a, CD11b, or CD11c	All leukocytes	
14	55	PI-linked	Monocytes, macrophages, some granulocytes	Dendritic reticulum cells in lymphoid tissues; some glandular epithelial cells of skin
15	Multiple bands	Lacto-N-fucopentose III (Lewis ^x)	Neutrophils, eosinophils, some monocytes	Some glandular epithelial cells; pituitary astrocytes; Reed Sternberg cells
65		Ceramide dodecasaccharide	Granulocytes	Hepatocytes; epidermis and sweat glands of skin; pancreatic secretory cells, bronchial epithelium; lung alveolar cells; renal tubular cells; colonic epithelial glands
66a	160–180	PI-linked glycoprotein Biliary glycoprotein 7	Neutrophils	Bile canaliculi; sweat glands, renal endothelium and some tubular cells; colonic epithelium
66b	95–100	PI-linked glycoprotein CGM-6	Granulocytes	
66c	90	PI-linked glycoprotein NCA	Neutrophils	Colon carcinoma
66d	30	PI-linked glycoprotein CEA	Neutrophils	
33	67	Transmembrane glycoprotein	Monocytes, some granulocytes	Myeloid progenitor cells; Langerhans cells
34	105–120	Transmembrane glycoprotein	None	Lymphohematopoietic stem cells; capillary endothelial cells
38	45		B cells and plasma cells; monocytes; activated T cells	Most lymphohematopoietic progenitor cells
16	50–70	Fc γ RIII	Neutrophils, macrophages, NK cells	Lymph node endothelium
32	40	Fc γ RII	Granulocytes, monocytes, B cells, some T cells platelets	Myeloid progenitor cells; some endothelial cells; some epithelial cells
64	70	Fc γ RI	Monocytes, some macrophages, neutrophils following interferon exposure	

Figure 1 Changing antigen expression during myelo-monocytic differentiation.

Other leukocyte antigens expressed by myeloid cells

Myeloid cells express many other antigens which are not usually considered as myeloid antigens. These include the HLA class I antigens expressed on all myeloid cells except mature red cells and the common leukocyte antigen (CD45) expressed on all leukocytes and early erythroblasts, but not intermediate or late normoblasts. The leukocyte cellular adhesion molecules (Leu-CAMs) or integrins are expressed on granulocytes and monocytes, the CD11b/CD18 complex being heavily expressed on granulocytes and monocytes, and the CD11c/CD18 complex being preferentially expressed on monocytic cells. The phagocyte integrins, in common with CD35 (CR1), CD15, CD10 and CD13, are stored in intracellular granules and are rapidly unregulated several-fold by a range of stimuli, including C5a, formyl-Met-Leu-Phe, tumor necrosis factor α (TNF α) and granulocyte-macrophage colony-stimulating factor (GM-CSF). All phagocytic cells express the low-affinity

Fc γ RII (CD32), as do many other cell types, including B cells, some T cells, and some endothelial and epithelial cells. The low-affinity receptor Fc γ RIII (CD16) is expressed on neutrophils and natural killer (NK) cells, and the high-affinity receptor Fc γ RI (CD64) is expressed on monocytes. Fc γ RI expression on monocytes is upregulated many-fold by exposure to interferon γ (IFN γ), and also becomes detectable on neutrophils following interferon treatment.

Functional aspects of myeloid antigens

The function of the leukocyte integrin molecules (CD11a, CD11b, CD11c, CD18) and the Fc receptors (CD64, CD32, CD16) are at least partly understood. As well as being involved in intracellular adhesion, CD11b and CD11c function as complement receptors (CR3 and CR4 respectively) and CD35 is the CR1 receptor.

Surprisingly little is known about the function of many of the other myeloid antigens. CD13 is an aminopeptidase N, which catalyzes the removal of

N-terminal amino acids from peptides with a preference for neutral residues. CD10 is a neutral endopeptidase (enkephalinase). It is thought that these surface molecules may cause hydrolytic inactivation of regulatory peptides and growth factors. Both molecules appear to modulate the phagocyte response to the bacterial cell wall peptide formyl-Met-Leu-Phe.

Various claims have been made for antibodies to many myeloid antigens either causing activation or inhibition of phagocyte functions. These must be viewed with caution, however, as most studies have been performed with intact antibodies which can simultaneously bind via their Fc portion to the various Fc receptors and effect signal transduction through these molecules.

NATURAL ANTIBODIES

Stratis Avrameas and **Thérèse Ternynck**, Department of Immunology, Pasteur Institute, Paris, France

That the sera of normal human beings and animals contain substances able to neutralize toxins or to agglutinate or lyse bacteria and erythrocytes was already well known at the end of the last century. It soon became evident that these substances corresponded to antibodies, and it was also rapidly established that sometimes these natural antibodies were able to react with constituents of the organism that produced them. Thus, natural antibodies toxic to spermatozoa or antibodies inhibiting the hemolytic action of erythrocyte-specific antibodies were found in the sera of various animal species. The results of Lansteiner and his group on the presence in normal human sera of antibodies specifically reacting with blood group substances, which led to the classification of human erythrocytes, were the beginning of a long series of studies on natural antibodies. With the passing years, it was shown that natural antibodies to bacteria, viruses, protozoa, parasites, heterologous and isologous erythrocytes, tissues and their extracts, tumors, toxins and spermatozoa were present in mammals, birds, reptiles, fishes and amphibians.

On the basis of the results obtained in these early studies, several conclusions were drawn. Two kinds of natural antibodies are present in sera. The first are specific and represent antigen-induced antibodies. Their formation depends on external antigenic stimuli and corresponds therefore to acquired specificities. The second most often, but not always, expresses a broad specificity, is genetically determined and does not depend on a given antigenic stimulation. Both kind of antibodies require permanent external antigenic stimulation for their maintenance. This stimulation is provided by related cross-reactive antigens. Natural antibodies to bacteria and viruses being widespread and present in all individuals, possess direct bactericidal and virus-neutralizing activities or, by binding to these pathogens, enhance their phagocytosis by macrophages and polymorphonuclear cells. Similarly antierythrocyte natural antibodies, by binding to effete erythrocytes, increase their opsonization and participate in their removal, while antitissue natural antibodies facilitate the elimination of tissue breakdown products. Based on this information, Grabar proposed that natural

antibodies, acting as carriers or transporters of self constituents, are part of the mechanism involved in the handling of metabolic and catabolic byproducts. Boyden advanced the concept that natural antibodies are the main means by which vertebrate and possibly invertebrate phagocytes discriminate between foreign and nonforeign matter.

Systematic studies on natural antibodies have been in progress since the beginning of the 1980s. They have benefited enormously from the recent intensive progress in immunobiotechnology. The main message of this new information is that the normal or preimmune repertoire is constituted principally of polyreactive antibodies able to recognize both self and nonself antigens equally well.

Occurrence and general characteristics of natural antibodies

A series of studies have shown that natural antibodies of the immunoglobulin M (IgM), IgG and IgA isotopes directed against an immense variety of antigens are present in normal sera of humans and other animal species including various fish of very distant phylogenetic orders (e.g. shark, torpedo, sturgeon and salmon). Internal, cell surface and circulating proteins, carbohydrates, nucleic acids, lipids and haptens are recognized by these natural antibodies. These constituents represent ubiquitous, self or highly conserved antigens and also environmental foreign antigens. IgM and IgG natural antibodies reacting with cell surface molecules of the immunoglobulin superfamily have been repeatedly detected in normal sera. Often IgG natural antibody activity was partially or completely masked in whole serum but it was unambiguously revealed after appropriate treatment of the serum. Depending on the antigen used, 5–100% of the normal sera examined were found to contain antibodies directed against a given antigen.

Human and mouse sera analyzed by means of ELISA or immunoblotting using homologous tissue extracts as the antigen source exhibited distinct IgM and IgG autoreactivity profiles. Two types of antibodies were found and isolated from normal sera: those that react with more than two, apparently unrelated antigens and those specific to a single antigen. Polyreactive antibodies are by far the most abundantly found in normal sera and usually possess low affinities. Monospecific antibodies behaved like the experimentally induced antibodies and usually possessed high affinities.

Similarly, B cell clones prepared from various human and mouse lymphoid organs during fetal and adult life secreted monoclonal natural antibodies

reacting with a wide variety of self and nonself antigens. Depending on the stage of development and the lymphoid organ, 2–100% of all the clones secreting immunoglobulins synthesized natural autoantibodies and, among them 2.5–100% reacted with two or more self and nonself antigens. The natural antibodies are produced by conventional B lymphocytes, although in some instances, it has been reported that Ly-1⁺ B cells were preferentially involved in their synthesis. Natural IgM autoantibody-producing B cell clones have also been obtained from nude, germ-free and antigen-free mice. Recently antibodies able to recognize self antigens with high specificity were isolated from a phage display library composed of the rearranged V genes of peripheral blood lymphocytes from a normal individual.

Properties and biological functions of natural antibodies

A series of studies has provided a better definition of several of the properties of natural antibodies. Polyreactive but also monoreactive natural antibodies are encoded by nonmutated or minimally mutated germ-line genes. Usually, but not always, natural antibodies possess low affinities but high avidities, and each one of them corresponds to the product of a single clone. Expression of natural antibody reactivity seems to be under the control of T cells.

Polyreactive natural antibodies carry common idiotypes and establish a dense idiotypic network among themselves early in ontogeny.

Natural antibodies have been reported to effect various biological functions (Table 1). Depending on the situation, they can play either a physiological, i.e. beneficial, or a pathological, i.e. harmful, role. Treatment of mice with idiotypically interconnected monoclonal antibodies or anti-idiotypic antibodies to natural antibodies results in an increase or decrease

Table 1 Biological functions of natural antibodies

Immunoregulation through idiotypic interactions
Immunoregulation by interacting with cytokines
Immunoregulation by interacting with B and T cells
Antigen processing and presentation by B lymphocytes
Rejection or protection of cellular engraftments
Interference with the development of autoimmune states
Induction of autoimmune-like syndromes
Induction of glomerulonephritis
Tumor inhibition or enhancement
Clearance of altered self constituents
Elimination or protection of pathogens
Expression of catalytic or inhibitory activities

of the immune response according to the idiotypes involved. In normal humans and mice, a natural antibody idiotype-like network exists that regulates the binding of IgG autoantibodies to self antigens, and this network is deficient in autoimmune states. Moreover, natural antibodies able to interact with molecules present on the surface of B and T cells have been shown to inhibit B cell growth or to suppress activation of T cell or autologous mixed lymphocyte reactions. Similarly, natural antibodies to various cytokines possess immunoregulatory functions.

B cells that bear natural antibodies as receptors have been shown to play an important role in the processing and presentation of antigens. Natural antibodies able to enhance tissue rejection but also, in contrast, to increase graft survival have been detected. By binding to altered self constituents, natural antibodies contribute to the clearance of catabolic products from the organism. Similarly, by reacting with pathogenic agents, they increase the opsonization of the latter by the reticuloendothelium system and contribute in their elimination from the organism. In some instances, natural antibodies can also inhibit the pathogenic effect by interacting with the host components rather than with the pathogen itself.

On the other hand, by binding to pathogens, natural antibodies focus the complement attack on non-lethal sites and protect the pathogen from destruction. Furthermore, they can even promote pathogenesis by mediating the internalization of the pathogens to gain access to its cellular niche. Likewise, depending on the situation, natural antibodies reacting with malignant cells enhance, retard or have no effect on tumor development.

Natural antibodies and pathological states

Recent studies have shown that there are extensive similarities between natural antibodies and the 'pathogenic' antibodies found in various immunopathological situations. Thus, in human and murine lupus, a substantial number of the autoantibodies against DNA which can be eluted from renal biopsies are able to react with many other antigens. Polyreactive IgM and IgG autoantibodies increase during the development of the murine lupus syndrome and form glomerular immune deposits. Furthermore, monoclonal polyreactive antibodies against DNA derived from lupus mice when injected into normal mice are able to induce nephritis. Many antibodies against DNA are encoded by nonmutated or minimally mutated genes but some show clear evidence of somatic mutations. These results suggest that in

lupus, high-affinity mutated 'pathogenic' DNA autoantibodies may arise from germ-line encoded low-affinity autoantibodies through an antigen-driven selection. However, germ-line encoded polyreactive natural antibodies without mutations may be pathogenic under certain circumstances.

Similar results were obtained and conclusions reached by analyzing the rheumatoid factor antibodies appearing in rheumatoid arthritis.

Recent studies have shown that antibodies produced after infections are often polyreactive and encoded by nonmutated germ-line genes. Thus, for example, analysis of the expressed V genes for IgG antibodies against herpes simplex virus and varicella-zoster virus showed that these antibodies use the same germ-line V_H genes used by autoantibodies. Similarly murine monoclonal antibodies reacting with group A streptococcal antigen were found to react with various autoantigens and to be encoded by unmutated germ-line genes. Furthermore, monoclonal antibodies obtained from *Trypanosoma cruzi*-infected mice reacting with this parasite were found to be encoded by the germ line and recognized antigens present on the membrane of activated T cells. It would appear, therefore, that infection by viruses, bacteria and parasites stimulates the natural antibody-producing cells, resulting in an increased synthesis of these antibodies.

NATURAL KILLER (NK) CELLS

Theresa L Whiteside, Department of Pathology, University of Pittsburgh, School of Medicine and University of Pittsburgh Cancer Institute, Pittsburgh, Pennsylvania, USA

Since their discovery in the early 1970s, natural killer (NK) cells have been recognized as a distinct subset of lymphocytes. Morphologically, they are large granular lymphocytes (LGLs) and functionally, they have the ability to kill a variety of cellular targets, including tumor cells and virus-infected cells, without damaging normal cells. The name 'NK cells' reflects the capability to kill susceptible targets spontaneously, i.e. without prior sensitization. For over two decades, NK cells have been considered to function as nonmajor histocompatibility complex (MHC)-restricted effector cells. Today, this functional definition of NK cells has to be modified. The family of recently discovered surface receptors on NK cells appears to regulate killing mediated by NK cells. The receptors recognize polymorphic class I MHC molecules expressed on target cells. The level of expression of HLA-A, -B or -C molecules on susceptible targets regulates their death or survival. The HLA-specific receptors are either inhibitory (killer cell inhibitory receptors, KIRs) or stimulatory (NK activating receptors, NKARs). The mechanisms responsible for this type of recognition and the molecular pathways mediating positive or negative signals generated upon interaction of the NK cell with its potential target are currently under intense investigations.

NK cells have important biological functions: in addition to selective elimination of abnormal targets (immune surveillance), they participate either directly or indirectly in multiple networks involved in development, regulation and communication within the immune system. They are found in the peripheral circulation as well as various lymphoid and nonlymphoid tissues. NK cells are remarkably

responsive to exogenous or endogenous activation signals by the rapid upregulation of cytolytic and proliferative functions as well as the production of numerous cytokines, including interferons, interleukin 1 β (IL-1 β), IL-10, IL-12, granulocyte-macrophage colony-stimulating factor (GM-CSF), tumor necrosis factor α (TNF α) and lymphotoxin (TNF β).

Activated NK cells express high levels of cellular adhesion and costimulatory molecules on the cell surface and acquire the ability to enter into solid tissues and to participate in interactions with tissue cells and extracellular matrix (ECM) components. These characteristics enable the NK cell to function as a highly efficient and aggressive effector cell, which is capable of modulating its own micro-environment and shaping the fate of neighboring cells. Understanding of the biology of NK cells is essential for defining their role in human disease.

Phenotype characteristics of NK cells

NK cells which are found in the human peripheral blood account for 5–15% of circulating lymphocytes and represent a minority of total body NK cells. In rodents, NK cells are more numerous in the spleen (10%) than in the peripheral circulation but can also be found under physiologic conditions in several nonlymphoid tissues, e.g. lung or intestinal mucosa. In some organs, e.g. the liver, NK cells represent up to 45% of tissue-associated lymphocytes. NK cells can be recognized and enumerated in blood or tissues by the use of monoclonal antibodies which recognize distinctive surface receptors on lymphocytes. In human peripheral blood, three subsets of NK cells can be thus identified: CD3⁺CD56⁺CD16⁺ (80–

90%); CD3⁻CD56⁺CD16⁻ (5–10%); and CD3⁻CD56⁻CD16⁺ (5–10%). However, both CD56 and CD16 markers are also found on the surface of other hematopoietic cells, and no membrane receptor unique for NK cells has been identified so far. To distinguish NK cells from other hematopoietic cells, it is, therefore, necessary to employ a panel of antibodies and to discriminate between the presence as well as the absence of certain surface markers. Thus, mature circulating human NK cells express the following phenotype: CD3⁻TCR⁻CD56⁺CD16⁺CD2^{dim}CD8^{dim}CD14⁻CD19⁻. They are distinguishable from T cells by the lack of T cell receptor (TCR) or of rearranged TCR genes, which retain the germline configuration in mature NK cells; from B cells by the lack of immunoglobulin (Ig) gene expression; and from monocytes by the absence of CD14 expression. Although NK cells do not produce Ig, they may bear surface Ig bound to FcR, which are expressed on most NK cells.

Activating receptors on NK cells

Similar to other lymphocytes, NK cells express a variety of surface receptors (R), which are responsible for interactions of the cells with soluble ligands, ECM components, and molecules expressed on the surface of surrounding cell types (Table 1). The majority of circulating human NK cells constitutively express IL-2R β and γ in the absence of IL-2R α (CD25) and bind IL-2 with intermediate affinity. Upon activation, NK cells produce CD25 *de novo* and rapidly upregulate expression of high-affinity IL-2R. While NK cells can proliferate in the presence of IL-2 alone, they require costimulatory signals in addition to IL-2 for optimal and sustained proliferation. Such costimulatory signals are delivered by other receptors, including cellular adhesion molecules (CAMs) and FcRs. The Fc γ RIII (CD16) is an activation receptor on NK cells, and its ligation by CD16-specific antibodies, immune complexes or tar-

Table 1 Activating receptors on NK cells^a

Receptor	Surface structure	Ligand	Effect on NK cell functions
NKR-P1	Type II lectin-like	Carbohydrate (?)	Recognition and lysis
Ly-49	Type II lectin-like	Class I MHC alleles (murine)	Recognition and lysis
CD94/p43	Type II lectin-like	Class I MHC alleles	Recognition and lysis
CD94/p39 (NKG2-C)	Type II lectin-like	? Molecules on some tumor targets	Recognition and lysis

^aThe list of activating or cytokine receptors expressed on NK cells is not all inclusive.

get cells bearing Ig results in antibody-dependent cellular cytotoxicity (ADCC), proliferation and cytokine production by NK cells. Engagement of the CD16 complex, consisting of CD16 and associated dimers of CD3 ζ -CD3 ζ ; Fc ϵ RI γ -CD3 ζ ; Fc ϵ RI γ -Fc ϵ RI γ on NK cells leads to activation of the intracellular signaling pathway similar to that induced by TCR-CD3 ζ activation in T cells. Importantly, the participation of antibody in this type of signaling confers specificity upon those NK cells that express Fc γ RIII. Some human NK cells also express Fc γ RIIc (CD32, isoform c), and it appears to be a signaling molecule on NK cells. The third type of FcR recently described, Fc μ R (receptor for IgM), is a triggering molecule expressed on the majority of NK cells. However, its cross-linking with IgM at physiological concentrations results in negative regulation of several NK cell functions, including cytotoxicity. A broad range of CAMs are detectable on NK cells (Table 1) and participate in signal transduction and activation of NK cells. For example, VLA-4 and VLA-5 (receptors for fibronectin) and VLA-6 (receptor for laminin) facilitate binding of NK cells to the relevant substrates and induce NK cell activation. Costimulatory molecules, such as CD2, CD69 or NKR-P1 may also be involved in triggering

of cytolytic function in NK cells. Monoclonal antibodies to these various surface molecules, acting as agonists, can initiate antibody redirected lysis of FcR-bearing targets (Figure 1d). Overall, it appears that cooperative engagement of several activating or costimulatory receptors interacting with their respective ligands on target cells is sufficient to induce a lytic pathway in NK cells.

Inhibitory receptors on NK cells

A novel class of receptors recognizing class I MHC molecules and capable of inhibiting lysis has been recently described on NK cells (Table 2). In rodents, the Ly-49 family of receptors expressed on NK cells includes at least eight distinct type II disulfide-linked homodimers of C-type lectins which bind H-2 class I ligands on target cells and inhibit NK cell-mediated lysis. In humans, a distinct family of killer cell inhibitory receptors (KIRs), which are type I transmembrane proteins of the Ig superfamily, has been identified. These receptors bind class I HLA molecules on target cells, and their ligation induces a negative signal and abrogation of the lytic process (Figure 1a). This function is mediated by phosphorylation of cytoplasmic tyrosines, which recruit the protein tyrosine phosphatase SHP-1. The absence

Figure 1 Interactions of NK cells with cellular targets do not result in lysis if the target cell expresses class I HLA molecules recognized by the HLA-specific receptor on the NK cell. Positive signals induced by binding of NKARs to their ligands on the target are superseded by negative signals transduced via KIRs, which bind to HLA alleles recognized on the target (A). If, however, expression of the HLA-alleles recognized by KIRs on the target is decreased or the target lacks these alleles, negative signals cannot be generated, and the target cell is lysed by the NK cells receiving positive signals via NKARs (B). In the presence of any antibody decorating the NK cell through Fc γ RIII and recognizing an antigen on the target, antibody-dependent cellular cytotoxicity (ADCC) leads to target cell lysis (C). If, however, the antibody decorates the target cell and also recognizes a signaling molecule on the NK cell, Ab-mediated redirected lysis occurs (D).

Table 2 Inhibitory receptors of NK cells (KIRs)^a

Receptor	Surface antigen structure	Ligand	Effect on NK killing
Ly-40 family	Type II lectin-like	Class I MHC alleles (murine)	Inhibition
p58	Type I IgSF (2D)	HLA-C alleles	Inhibition
p70 (NKBI)	Type I IgSF (3D)	HLA-BW4 alleles	Inhibition
p140	Type I IgSF (3D) Ig-like protein (3D)	HLA-A alleles	Inhibition
CD94/kp43 (NKG2-A)	Type II lectin-like	Class I alleles	Inhibition

D, Ig domain; IgSF, immunoglobulin superfamily.

^aInhibitory receptors on NK cells contain xY/xL sequences in the cytoplasmic tail, which are termed immunoreceptor tyrosine-based inhibiting motifs (ITIM) and which are necessary for inhibitory function.

of class I HLA molecules or their decreased expression on target cells leads to NK cell-mediated lysis of the target (**Figure 1b**). KIRs belong to a large and diverse family of receptors, which appear to be distributed in different combinations on distinct NK cell clones and NK cell subsets. This family also contains MHC receptors which activate rather than inhibit NK cytotoxicity, e.g. the p50.3 receptor involved in HLA-C recognition in humans (**Table 1**). Furthermore, MHC receptors have been detected not only on NK cells but also on subsets of T cells. The presence of both inhibitory and stimulatory MHC receptors on the same NK or T cell indicates that immune responses are regulated by maintaining a delicate balance between positive and negative signals induced upon recognition of MHC alleles on target cells.

Functional Characteristics of NK cells

Lysis of target cells

The ability to recognize and lyse a broad range of targets with altered surface expression of MHC molecules, such as virally infected or transformed cells or certain allogeneic targets, is the fundamental functional attribute of NK cells. While the molecular events involved in the process of target recognition and signaling remain to be clarified, cellular alterations which result from effector (E)–target (T) cell interactions are known. Several distinct and sequential steps are involved in the process of lysis, as indicated in **Figure 2**. Human NK cells can utilize two different and independent mechanisms of killing: secretory (necrosis) and nonsecretory (surface receptor-mediated apoptosis). NK-sensitive targets, such as K562, are predominantly killed by necrosis. In contrast, NK-resistant targets, such as fresh tumor or solid tissue cells, are killed only by apoptosis in the absence of demonstrable necrosis. Activated NK cells can rapidly kill a broad range of targets by a combination of these two mechanisms. The NK cell

**Figure 2** Schematic representation of the mechanism of lysis of target cells by NK cells.

which survives a lytic event is able to recirculate, that is, it can bind to another susceptible target and kill it. The efficiency of NK cell-mediated lysis is dependent on the ratio of E:T present, state of NK cell activation, and sensitivity of the target cells to lysis.

Response of NK cells to cytokines

Among lymphocytes, NK cells are the first to respond to activation by IL-2, because they constitutively express the β chain of IL-2R. Consequently, incubation of peripheral blood lymphocytes with IL-2 induces selective activation of NK cells and results in rapid upregulation of NK cell activity and, later, generation of LAK cell activity and proliferation. In the presence of IL-2, a small subset of NK cells (10–30%) rapidly (within minutes) acquires the ability to adhere to plastic or other solid surfaces *in vitro*. These cells are almost exclusively CD3⁺CD56^{dim}CD16^{dim} or CD16⁺, and they respond to relatively high levels of IL-2 by rapid upregulation of the IL-2R β chain, β_2 -integrins and activation antigens on the cell surface and by *de novo* expression of the IL-2R α chain. These NK cells also upregulate expression of mRNA for a variety of cytokines. These cells have been named 'A-NK' cells, 'A' standing for the adherence and activation that characterize their early response to IL-2. The property of adherence to plastic can be reliably used to isolate and

culture A-NK cells from human peripheral blood or spleens of rodents.

All NK cells undergo activation and expansion in the presence of IL-2 and/or other cytokines (e.g. IL-6, IL-12 and IL-15). NK cells which are derived from bone marrow precursors, can be generated *in vitro* by culture of CD34⁺ bone marrow cells with IL-2. Activated NK cells, and especially the subset of A-NK cells, become highly mobile and develop membrane structures called podosomes, which facilitate movement along solid surfaces and binding to tissue cells or to ECM. A-NK cells show significantly increased integrin-mediated adhesion to fibronectin- or laminin-coated plates and increased binding to human umbilical vein-derived endothelial cells (ECs) cultured on type I collagen. Associated with this increased adhesion and mobility of A-NK cells are changes in expression of activation markers and CAMs on the cell surface, upregulation of mRNA levels for cytokines, increased adhesiveness to ECs and transendothelial migration as well as highly augmented cytotoxicity.

NK cells in intercellular communication

A variety of soluble factors produced by activated NK cells are responsible for the importance of NK cells as mediators or effectors of the intercellular communication network. Activated NK cells produce a spectrum of cytokines: hematopoietic cell growth factors, interferons, interleukins, TNF α , lymphotoxin, TGF β and other growth factors. Enzymes produced by NK cells, especially those associated with the cell membrane, play an important role in cell-to-cell interactions and NK cell migration within tissues. A-NK cells also express, and upregulate upon activation, the receptors for a variety of chemotactic factors, cytokines, growth factors and hormones, including neuropeptides. This allows them to respond to signals generated not only within the immune system but also elsewhere in the body.

Regulation of NK cell functions

The functions of NK cells have to be carefully regulated, because of the potential for tissue damage by inappropriate cytokine release and/or lysis. While the ability to swiftly respond to antigen-independent stimuli is obviously advantageous for the effector cell, it also requires a regulatory 'check and balance' system. This is in part achieved by controls operative at the receptor level and resulting in positive or negative signals received and processed by the cell, presumably depending on its external environment. Also, NK cell functions are controlled at the level of development, differentiation and availability of effec-

tor cells at a particular site. The number of NK cells present at the site of tissue injury, for example, is a function of their ability to migrate and proliferate. Cytokines and chemokines generated by tissue and/or hematopoietic cells modulate NK cell availability and their activity *in vivo*. The development of NK cells from the lymphoid cell precursor in the bone marrow depends on soluble factors produced by stromal cells in the marrow and on cytokines produced by T and B lymphocytes. NK cell maturation from their precursors present in the blood, spleen or other lymphoid organs is also dependent on a mix of cytokines produced by other hematopoietic cells. In addition, subsets of T cells may be able to down-regulate NK cell functions.

The biological importance of NK cells

Table 3 indicates that NK cells may participate either directly or indirectly in a variety of essential biological processes, ranging from reproduction to immunoregulation. While there is evidence for the involvement of NK cells in various physiological pathways, the mechanisms responsible for many of the NK cell-mediated effects are not entirely clear. For example, NK cells have been shown to mediate antiviral, antifungal and antibacterial activity *in vitro*. Their *in vivo* importance in control of infections is supported by studies of experimental viral infections in mice and by reports correlating low NK activity with increased sensitivity to frequent and severe disseminating viral infections in humans, including herpes simplex virus (HSV), Epstein-Barr virus (EBV) and cytomegalovirus (CMV) infections. *In vivo* responses of NK cells to a viral challenge involve upregulation of cytotoxicity, proliferation, migration of NK cells to infected tissues and production of IFN γ .

IL-12 is a potent inducer of IFN γ production by NK cells. Virus-induced interferons (IFN α/β) upregulate NK cell functions and also modulate IL-12 expression, contributing to the development of an antiviral milieu early on during infection and prior

to the appearance of virus-specific T cells. Activated NK cells may reduce viral replication by killing infected host cells, and they are able to produce a variety of cytokines which can inhibit viral replication as well as facilitate antigen processing and presentation by increasing expression of HLA molecules. NK cells have been long recognized as effectors responsible for elimination of bloodborne metastases. Newer evidence obtained in experimental studies in rodents suggests that activated NK cells play an important role in both limiting local tumor growth and prevention of metastasis development. In particular, A-NK cells, which are able to enter solid tissues, migrate to sites of metastasis and eliminate malignant targets but spare normal tissue cells, appear to have all the attributes of ideal anti-tumor surveillance as well as effector cells.

The observation that NK cells accumulate in substantial numbers at the maternal-fetal interface has led to the speculation that uterine NK cells play an important role in pregnancy. More recent data confirm that NK cells have both a trophic and regulatory role in the growth of the fetal-placental unit. Through cytokine production, uterine NK cells apparently influence trophoblast behavior at the implantation site early in pregnancy, and through release of cytolytic and hydrolytic enzymes, they may contribute to separation of the placenta at parturition. On the other hand, protection of the trophoblast from lysis by uterine NK cells may be regulated at the level of expression on trophoblast cells of HLA-G and HLA-C molecules, which engage KIRs on NK cells and prevent lysis.

The involvement of NK cells in the regulation of hematopoiesis is due to their ability to produce a spectrum of cytokines, including colony-stimulating factors (CSF) and other growth factors, necessary for the differentiation of hematopoietic cells. In addition, subsets of NK cells have been described in mice, which can positively or negatively regulate hematopoiesis. Expression by these subsets of different Ly-49 alleles may determine their hematopoietic growth-promoting or -inhibitory functions. NK cells participate in immunoregulation by virtue of cytokine secretion in response to stimulation by endogenous or exogenous stimuli. NK cells can secrete immunoinhibitory cytokines, such as IL-10 or TGF β and through TNF α , lymphotoxin or FasL-mediated interactions with activated T cells can induce apoptosis of those immune cell subsets that are responsible for immunoregulation.

Finally, interactions of NK cells with the neuroendocrine system have achieved considerable attention recently. NK cells express receptors for neuropeptides, opioids, prolactin and other hormones

regulating interactions between the brain and the immune system. Therefore, NK cells are highly responsive to changes in the serum levels of these hormones. Effects of stress on the immune response can be monitored by serially following changes in NK cell activity. For example, inability to deal with stressful life events in otherwise healthy individuals is associated with low NK cell activity. Also, a possibility exists for homotypic interactions between NK and brain cells via neural cellular adhesion molecules (NCAMs, e.g. CD56 or CD57) expressed on both.

With the NK cell involvement in a number of biologically important interactions, it is essential that NK cell activity remains under stringent and finely tuned control. The danger of unsolicited lysis or release of inappropriate cytokines by A-NK cells is regulated at several levels. First, the immune system itself is capable of downregulating NK cell functions by engaging regulatory T cell subsets. Second, a system of inhibitory and stimulatory receptors present on NK cells allows for environmental control of NK cell responses, including cytotoxicity and cytokine production. Third, the availability of NK cell precursors at a relevant site and their ability to differentiate and proliferate *in situ* is likely to be dependent on the chemokine and cytokine milieu, representing a sensitive and effective control mechanism. Since NK cells may be called to action early in the course of an immune response, their rapid mobilization is essential, but the subsequent termination of their functions, which may be dangerous to other cells, has to be rigorously implemented. When one or more of the redundant control mechanisms fail, disease may ensue.

NK cells in disease

Human diseases associated with NK cell abnormalities can be categorized as NK cell deficiencies or excessive NK cell activity. In either case, only chronic abnormality in NK cell activity is considered pathologic, because transient changes accompany a variety of physiologically normal events (e.g. circadian variations, daily stress, exercise or common cold). In every individual, NK activity fluctuates over time, but it can be quite precisely defined as a baseline level of NK cell activity $\pm$ SD by performing serial NK cell assays. The baseline level of NK cell activity is a characteristic trait for every individual. On the other hand, persistently low or high levels of NK cell activity are likely to be associated with disease. Chronically low levels of NK cell activity are seen in cancer, acquired or congenital immunodeficiency diseases (e.g. acquired immune deficiency syndrome, AIDS), severe life-threatening viral infections (HSV.

EBV, CMV), a subset of patients with chronic fatigue syndrome (CFS), certain autoimmune diseases (e.g. connective tissue diseases) and behavioral disorders (e.g. depression).

Persistently elevated NK cell activity is relatively rare, being reported in autoimmune liver diseases, including viral hepatitis, and in NK cell lymphoproliferations. The latter present as elevations in the number of activity of NK cells or both and are characterized by a benign course, lymphocytosis of LGLs, cytopenias and splenomegaly. Rare acute proliferations of LGL have been reported and are consistent with aggressive leukemia/lymphoma.

Persistently low levels of the NK cell number or activity in patients with advanced metastatic or other diseases may be associated with more severe symptoms or increased risk of disease progression. Therefore, it may be advantageous for patients with chronically low NK cell activity to receive therapy designed to augment NK cell functions. Such therapies are available today and consist of: 1) administration of agents known to upregulate endogenous NK activity (e.g. interferons, IL-2 or IL-12) or 2) adoptive transfer of autologous A-NK cells either systemically or locoregionally.

Measurement of NK cells

NK cell activity and the number of NK cells are measured in the peripheral blood in humans and in the spleen in rodents. A short-term (4 h) ^{51}Cr -release assay is used to determine NK cell activity, with a standard number (5×10^3) of cultured K562 cells as targets (T) and peripheral blood mononuclear cells (PBMCs) as effectors (E). The latter are adjusted in number to give at least four different E:T ratios, thus allowing for generation of a lytic curve by plotting the per cent specific lysis measured at each E:T ratio. The results of NK cell assay are usually expressed as lytic units (LU) calculated from the lytic curve and defined as the number of effector cells required to kill 5×10^3 targets in a batch of tested cells. Computer programs are available to facilitate transformation of the per cent specific lysis into LU.

Using variations of this cytotoxicity assay by the addition of antibody or by changing the target, it is possible to measure ADCC or spontaneous LAK activity, respectively. The measurement of the NK cell number should be performed at the same time as the NK cell assay, because both are necessary for an adequate evaluation of natural immunity or for following its changes during disease or therapy. To determine the number of NK cells, PBMCs are stained with labeled monoclonal antibodies specific for NK cell-associated markers (e.g. CD56 or CD16

in humans; NKR-P1 in rats and NK1.1 in mice) and the percentage of positive cells in a population is determined by flow cytometry. This percentage value is then converted into the absolute number of NK cells, based on a simultaneously obtained differential lymphocyte count. A variety of assays are available for assessment of NK cell functions other than lysis. For example, generation of LAK activity *in vitro*, proliferation, cytokine production, migration, binding to substrates, ability to induce apoptosis or to transduce signals can be accurately measured provided purified NK cells are available. Negative selection with immunobeads is generally used to obtain highly enriched preparations of NK cells for these assays.

NEISSERIA, INFECTION AND IMMUNITY

Catherine Ison and **Brian Robertson**, Department of Medical Microbiology, Imperial College School of Medicine at St Mary's, London, UK

The genus *Neisseria* belongs to the family Neisseriaceae and contains 12 species, of which only *N. gonorrhoeae* and *N. meningitidis* are considered primary pathogens. Although these two species share 80% DNA homology they cause diverse types of infections. *N. gonorrhoeae* causes primarily a mucosal infection of the urogenital tract known as uncomplicated gonococcal infection (UGI). In a few patients, complicated gonococcal infection presents as pelvic inflammatory disease (PID) in women and as epididymitis and prostatitis in men. Disseminated gonococcal infection is rare and presents as septicemia, rash or arthritis. It is more common in women and is associated with strains that are highly susceptible to penicillin and require arginine, hypoxanthine and uracil for growth. *N. meningitidis* colonizes the mucosa of the upper respiratory tract as a commensal and encapsulated strains can cause systemic infection resulting in meningitis. *N. gonorrhoeae* and

N. meningitidis are obligate human pathogens and have no other natural reservoir.

Neisseria spp. are gram-negative diplococci, produce cytochrome c (oxidase) and utilize carbohydrates by the oxidative pathway. *N. gonorrhoeae* utilizes only glucose whereas *N. meningitidis* utilizes both glucose and maltose. They require complex media for growth and are enhanced by 5–7% carbon dioxide.

The neisserial cell envelope consists of a cytoplasmic membrane, a thin peptidoglycan layer and an outer membrane. The main outer membrane antigens of *N. gonorrhoeae* and *N. meningitidis* are listed in Table 1.

N. gonorrhoeae can be divided into serovars dependent on the antigenic specificity of Por which occurs in two types, PIA and PIB. Gonococci belonging to PIA serovars are more susceptible to antibiotics and PIB more resistant. Encapsulated strains

OMP, outer membrane protein.

of *N. meningitidis* have been subdivided into 13 serogroups by the difference in the composition of the capsular polysaccharide. The most prevalent serogroups in disease are A, B, C, W-135 and Y. Meningococci can be further divided into serotypes based on the antigenic specificity of the outer membrane proteins, which is independent of the serogroup. Commensal meningococci are invariably nonencapsulated and piliated, whereas invasive meningococci are encapsulated and nonpiliated; phase variation of these antigens occurs, and may allow switching between phenotypes.

Immune response of the host

Patients with gonococcal infection show increased levels of serum and mucosal gonococcal-specific antibody. Both immunoglobulin G (IgG) and IgA are directed at surface exposed antigens described in Table 1. Protective immunity is not acquired by natural infection and patients presenting with multiple episodes of UGI are common. This may be due to the antigenic heterogeneity of the surface antigens or because the mucosal antibody response is short-lived and serum antibody has no function in the mucosal infection. The ability of gonococci to attach and colonize the mucosa and their interactions with polymorphonuclear neutrophils may be more important than the immune response in UGI. Repeated episodes of PID occur, but women are not reinfected with strains of the same Por serotype. In contrast, protective immunity to meningococcal infection is known to be correlated with the presence of complement-dependent, bactericidal antibodies in the serum directed against the capsular polysaccharide.

Children under 2 years of age do not reliably produce antibodies either to natural infection or to immunization with meningococcal polysaccharides. In addition, patients with an inherited deficiency of one of the terminal components of the complement pathway are also susceptible. There is little evidence for a cell-mediated immunity.

Evasive strategies by the organism

Surface antigens of *N. gonorrhoeae* such as pilin, Opa and LPS undergo phase and antigenic variation. The range of molecules expressed determines a number of crucial bacterial phenotypes related to infection. Antigenic variation *per se* promotes evasion of host immune defenses, facilitating repeated infection. Tissue tropism depends on the combination of Opa and pilin molecules expressed. *In vivo* gonococci expressing particular sialylated lipopolysaccharide

(LPS) molecules are serum resistant, but unable to evade epithelial cells. Antigenic variation can also produce an LPS that cannot be sialylated – such organisms are invasive. Sialylated LPS molecules mimic eukaryotic cell surface markers, compromising recognition by the host immune system. *In vitro* most strains become serum sensitive due to the absence of the sialic acid donor, although some gonococci do remain resistant, suggesting an additional unidentified mechanism. Serum-resistant gonococci show reduced development of C5 convertases in normal human serum. Naturally occurring IgG and antibodies to Rmp can block complement-mediated killing.

Repeated infection with *N. meningitidis* is rare because specific immunity is protective and re-exposure to a strain expressing a different polysaccharide capsule is uncommon. Phase and antigenic variation is exhibited in a similar manner to gonococci for many surface molecules common to both species. In addition, phase variation of the capsule occurs, both by the insertion of a transposable element in a sialic acid biosynthesis gene, and by slipped-strand mispairing in the polysialyltransferase gene.

Both *N. gonorrhoeae* and *N. meningitidis* produce a protease that cleaves human IgA1. It is presumed to be a virulence factor but its role in pathogenesis is still unclear.

Vaccines

No successful gonococcal vaccine has been produced. This is due to the antigenic heterogeneity of the antigens chosen as candidate vaccines and because the type or amount of antibody required to produce protection is unclear. There is also no animal model that correlates with human infection. Pilin vaccines have proved unsuccessful. Por- and iron-binding proteins are still considered potential vaccine candidates, particularly for preventing complicated infection in women. Polysaccharide vaccines to *N. meningitidis* of serogroup A and C have been shown to produce bactericidal antibodies and to be protective, although this response is age-dependent.

A vaccine incorporating polysaccharide from serogroups A, C, Y and W-135 is now available and should stimulate bactericidal antibodies in 90% of adults. In order to increase the immunogenicity in young children the polysaccharide A and C vaccine has been conjugated to protein carriers such as tetanus toxoid. Many cases of meningococcal disease are caused by serogroup B strains and polysaccharide vaccines do not elicit protection. This has been attributed to its poor immunogenicity or the similarity

between the polysaccharide and sialic acid moieties in human tissue.

Protection against serogroup B strains may be associated with antibody to outer membrane proteins (OMPs). OMPs have been used either alone or in combination with polysaccharide in attempts to produce immunity. Vaccines that have been used or are in clinical trials include LPS-depleted OMs of serotype 15 subtype P1.16 (Norwegian), LPS-depleted outer membrane (OM) vesicles from serotype 4, subtype P1.15 together with serogroup C polysaccharide and a high molecular weight protein complex (Cuban) and a hexavalent class 1 OMP vaccine (Dutch). Their efficacy in young children still needs to be clarified.

NEONATAL IMMUNE RESPONSE

Richard L Riley, Department of Microbiology and Immunology, University of Miami School of Medicine, Miami, Florida, USA

Both humoral and cellular immune responses of neonatal individuals differ in quality and quantity from those of adults. Early in ontogeny, these differences may result from the lower incidences and/or decreased functions of immunocompetent cells (e.g. B cells, T cells, antigen-presenting cells).

B lymphocyte development and function in the neonate

Pre-B cells express cytoplasmic μ chain and lack surface immunoglobulin (Ig). In humans, pre-B cells are detected in fetal liver and omentum as early as 7–8 weeks of gestation. One to two weeks later, B lymphocytes (surface IgM⁺) are found in fetal liver and the development of B lymphocytes expressing other surface Ig isotypes follows. In the mouse, the earliest B lineage precursor cells can be identified as CD45R (B220)⁺ cells in fetal liver at ~12–13 days gestation. B lineage cell development also involves the surrogate light chains, (e.g. $\lambda 5$, VpreB) which are

expressed both in pro-B cells and, as a complex with μ chain, in pre-B cells. Surrogate light chain ($\lambda 5$) transcription is seen by day 13 in fetal liver and pre-B cells are evident by day 14. Pre-B cells exhibit heterogeneity in surface antigen expression (e.g. CD43) and in expression of other molecules (e.g. RAG-1, RAG-2) indicative of their activity and precise stage of maturation. B lineage precursors from adult mice differ from those seen early in ontogeny. For example, murine fetal pre-B cells do not express major histocompatibility complex (MHC) class II antigens, in contrast to adult pre-B cells. B cells are clearly demonstrable in murine fetal liver by days 16–17 of gestation; these fetal B cells are generally restricted to expression of surface IgM. Eventually, the bone marrow becomes the main organ of B lymphopoiesis in both mouse and human throughout adult life.

IgM synthesis has been detected as early as 10–12 weeks of gestation in the human fetus; however, serum concentrations of IgM in the newborn are

approximately 10% of those observed in adults and do not reach adult levels until 1–2 years of age. Serum concentrations of nonmaternal IgG are also abnormally low in the neonate and do not approach adult concentrations until 4–6 years of age.

Developmentally, immunocompetence does not extend to all antigens and, early in ontogeny, humans are constrained in their capacity to mount humoral responses to carbohydrate antigens. Children less than 2 years of age are generally deficient in response to unmodified bacterial polysaccharide vaccines. This, in turn, may contribute to the susceptibility of infants to certain bacterial infections (e.g. *Streptococcus pneumoniae*).

Fetal/neonatal B cells exhibit a restricted antibody repertoire

It has been shown that the fetal/neonatal repertoire of available antibody specificities is restricted. The development of antibody specificities during ontogeny proceeds in a temporally dependent and programmed manner. BALB/c mice possess B cells capable of responding to the hapten dinitrophenyl and to the carbohydrate antigen β 2,6-fructosan by day 1 after birth; however, reproducibly, those B cells bearing the T15 idiotype and responsive to the antigen phosphorylcholine are only apparent at ~1 week after birth. As a consequence of this pattern of antibody repertoire acquisition, the developing neonate has a more limited spectrum of available B cell specificities which diversifies in a predictable fashion.

Studies in both human and mouse indicate that fetal and neonatal pre-B and B cells exhibit biased recombination and expression of those immunoglobulin heavy-chain variable region (V_H) gene families located most proximal to the D_H and J_H gene segment loci. Early in ontogeny, the enzyme terminal deoxynucleotidyl transferase (TdT) is limited. Lack of TdT, by restricting junctional diversity, also contributes to decreased Ig repertoire complexity. Although the decreased diversity present in the emerging B cell repertoire could contribute to the failure to respond to particular antigens as discussed above, this need not be the case. For example, as discussed by Schroeder and colleagues, the V3–23 immunoglobulin heavy-chain variable region gene in humans is a major contributor to the fetal repertoire and yet encodes specificities to antigens some of which (e.g. polysaccharides) are not responded against until ~2 years of age. This suggests that the more limited capacity to respond to the spectrum of antigens early in ontogeny and the programmed readout of the functional immune repertoire is due

to complex mechanisms of which V_H gene usage is only one component.

The composition of B cells within the developing neonate may also contribute to constraints on immune function. B cells are divisible into subpopulations based on the expression of surface antigens. In both human and mouse, a subset of B cells (B1 cells), many of which express the CD5 surface antigen, is more prominent early in ontogeny. It has been shown that the CD5 B cells represent a separate B cell lineage with precursors distinct from those which yield the conventional (CD5⁻) B2 cell population which dominates the peripheral B cell compartment in the adult. Notably, precursors of CD5 B cells are present early in fetal/neonatal life, but are not derived from adult bone marrow. In both human and mouse, CD5 B cells may be biased toward recognition of self and environmental antigens and also exhibit degenerate specificity. Differences in the composition of the B cell compartment between neonates and adults may also contribute to differences in their humoral immune capabilities.

Antibodies generated from murine neonatal spleen demonstrate an unusual capacity for recognizing idiotypic determinants on each other ('connectivity'). The neonatal antibody repertoire, although restricted in diversity, is skewed toward reactivity with self molecules, including idiotypic determinants present on immunoglobulins. This has led to the hypothesis that neonatal B cell responses may be of importance in establishing an immune network.

T cell development and function in the neonate

In humans, at approximately 7 weeks gestation, bloodborne stem cells enter the developing thymus. Similarly, in the mouse, hematopoietic cells enter the embryonic thymus by day 11 of gestation. In both mouse and human, the initial thymocyte populations are comprised of lymphocytes lacking expression of either the CD4 or CD8 molecules as well as T cell antigen receptors (TCRs). Rearrangement of TCR gene segment loci rapidly ensues with subsequent appearance of surface TCR-bearing T cells. Notably, early in development at the double-negative phase, expression of a functionally rearranged V_β chain together with the pre- T_α chain and CD3 provides a complex which favors further development and expansion. Initially, the majority of thymic T cells express TCR of the γ/δ type at ~14–15 days gestation in the mouse and ~9.5 weeks gestation in humans; however, by 20 days of murine and ~10 weeks of human gestation, T cells bearing α/β TCRs gain predominance as is typically observed in the

Table 1 B cell properties during ontogeny

	Fetal/neonatal B cells	Adult B cells
Ig combining site repertoire	Restricted V _H , V _L usage Restricted N region diversity	Random V _H , V _L usage Extensive N region diversity
B cell subsets	B1 and B2 B cells	Mainly B2 B cells; Few B1 B cells
Isotypes produced during an immune response	IgM>IgG	IgG>IgM
Tolerance induction	Sensitive	Resistant
Self-reactivity/connectivity	High	Low

adult. Although some studies suggest that the T cell repertoire may be less diverse in the early human fetus and in fetal/neonatal mice, the murine splenic cytotoxic T cell precursors specific for particular MHC class I alloantigens in 8-day-old neonatal mice are similar in diversity to those of adults.

The capacity of T cells in both neonatal mice and humans to provide help for immunoglobulin secretion is limited mainly to IgM production. T cell helper function in the neonate is often difficult to quantitate due to the activation of suppressor T cells. Furthermore, both the rejection of MHC allogeneic cells as well as responses in mixed lymphocyte cultures and cytotoxic activity may be diminished in neonatal mice as compared to adults. In contrast to these reduced T cell functions, neonatal spleens are enriched in T cells capable of vigorously suppressing a variety of immune responses *in vitro* and *in vivo*. Both lymphocyte proliferation and immunoglobulin production are affected by neonatal suppressor T cells. The subset of T cells responsible for neonatal suppression is not clear and both CD4⁺ and CD8⁺ T cells have been implicated. In humans, the capacity to mount suppressive responses is prevalent throughout early life (e.g. in 8 weeks gestation liver) and begins to wane rapidly by ~1 year of age.

CD4⁺ T cells provide help to B cells and promote inflammatory reactions (delayed-type hypersensitivity). These functions are mediated largely by cytokines released upon T cell activation. Adult T cells produce a diversity of cytokines, including interleukin 2 (IL-2), IL-4, and interferon γ (IFN γ); however, T cells from neonates produce decreased levels of IL-2 (e.g. upon stimulation with anti-CD3 antibodies) as well as substantially lower levels of both IL-4 and IFN γ . The reduced production of these cytokines may contribute to diminished activation and/or maturation of macrophages, natural killer (NK) cells, and cytotoxic T cells as well as reduced help to B cells. Decreased help for B cell responses may also be reflected in the paucity of CD40 ligand on the surfaces of activated neonatal T cells; CD40 ligand, interacting with B cell CD40, functions in

promoting B cell help. The impaired activation of T cells may result from abnormalities in antigen uptake, processing, and/or signaling by appropriate antigen-presenting cells. With regard to the latter possibility, it is of interest that in early development, macrophage/monocytic cells exhibit decreased surface densities of class II MHC antigens which may impair appropriate antigen presentation to T lymphocytes. It has also been suggested that reduced incidence of memory T cells in neonates contributes to their decreased function, presumably a consequence of the antigenically naive status of the neonate.

Although the above studies indicate that fetal/neonatal T cell immunity is deficient, recent studies by Sarzotti and coworkers suggest that neonatal T cells can generate protective cytotoxic T cell responses dependent upon the dose of antigenic virus employed. Ineffective cytotoxic T lymphocyte (CTL) responses to high doses of virus reflected establishment of T_H2 (type 2) immune responses in the neonates. Therefore, immune 'deficits' in the neonate may actually represent deviations of the immune response.

Tolerance induction among neonatal lymphocytes

Neonatal lymphocytes, in contrast to their adult counterparts, are exquisitely sensitive to inactivation following occupation of their antigen-specific surface receptors. The inactivation of neonatal lymphocytes may occur via clonal abortion or deletion or, alternatively, by clonal anergy. The sensitivity of neonatal T and B lymphocytes to tolerance induction is probably of considerable importance in purging high-affinity autoreactive lymphocytes. However, these results have recently been challenged by Ridge and colleagues and Forsthuber and coworkers, wherein neonatal T cell tolerance versus activation was shown to be malleable and is likely to be more dependent upon the characteristics of antigen-presenting cells rather than on the T cells themselves.

Table 2 T cell properties during ontogeny

	Fetal/neonatal	Adult
TCR repertoire	Limited (?)	Extensive
T cell subsets	$\gamma\delta$ and $\alpha\beta$ T cells	$\gamma\delta$ and $\alpha\beta$ T cells
T cell suppression	High	Low
CD4 ⁺ T cells:		
Cytokines produced upon activation	Low levels of IL-2, IL-4, and IFN γ	High levels of IL-2, IL-4, and IFN γ
Expression of CD40 ligand	Low	High

Summary

Both T and B cell functions may be more limited early in ontogeny than in adulthood (Tables 1 and 2). In part, this may reflect restrictions imposed on the diversity of the antigen-specific repertoires; however, differences in responses to various modes of activation by neonatal and adult lymphocytes also contribute to differences in immune outcome. The differences seen in immune responses to antigens early in ontogeny as opposed to that in adult life is of consequence in both host immunity to microorganisms and in development of appropriate vaccine strategies.

NEPHELOMETRY

Lars-Åke Nilsson, Department of Medical Microbiology and Immunology, University of Göteborg, Göteborg, Sweden

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Nephelometry (Gr. *nephele*, cloud), also called immunonephelometry, is a method suitable for the quantitative determination of proteins and other biological substances. It is based on the precipitin reaction in fluid medium, whereby the reaction between an antigen and its corresponding antibody results in the formation of small antigen-antibody aggregates, which successively develop into floccules or precipitates. Detection of the antigen-antibody complexes formed is accomplished by measurement of the amount of scattered light at an angle to an incident beam passed through the solution. This principle differs from that of turbidimetry in which residual transmitted light is measured. Devices for the quantitative measurement of light scattered by particles in a fluid, nephelometers, were introduced on a more commercial basis in the early 1970s.

Characteristics of the precipitin reaction

The interpretation of results obtained by nephelometry requires an understanding of the course of the precipitin curve. The antigen-antibody reaction in a fluid medium may be considered as consisting of two phases, one rapid initial reaction with the formation of small molecular complexes, followed by a slower reaction in which nonspecific aggregation of the primary antigen-antibody complexes occurs. One of the characteristics of the precipitin curve is the direct relationship between the amount of antigen added and precipitate formed, providing that the reaction is performed with antibody in excess. With further addition of antigen, antibodies successively become saturated and the amount of precipitate formed levels off or eventually decreases (see Figure 1). The course of the precipitin curve in the antibody excess region varies for different types of antisera and is largely dependent on the animal species used for immunization. The precipitin reaction is fairly independent of temperature as well as variations of pH in the range pH 6–8.

Increasing ionic concentration generally decreases the strength of the binding between antigen and antibody and thereby the amount of precipitate formed, although with immune sera produced in chickens for example, immunoprecipitation is enhanced when performed at a high ionic strength. The finding that the addition of polymers, such as polyethylene glycol, enhanced the precipitin reaction by decreasing

Figure 1 Schematic representation of the precipitation curve. The curve represents the amount of precipitate formed when increasing amounts of an antigen are added to a constant amount of the corresponding antibody.

the solubility of immune complexes has been of decisive significance in the commercial development of nephelometric techniques.

Light scattering by immune complexes

When the precipitin reaction is performed under proper conditions, the amount of light scattered will be directly related to the reactant concentration. A prerequisite for this is that the reaction is performed with one of the reactants, usually the antibody, in excess. A given antigen concentration will then result in a given amount of immune complexes and consequently a given amount of scattered light. At high antigen concentrations, however, when the precipitin curve approaches the equivalence zone or eventually proceeds into the antigen excess zone, the scatter response is no longer linear.

The light-scattering properties vary in different patients' sera, and in order to circumvent this problem, subtraction of individual serum blank values is required for each separate analysis. High blank values may be due to lipemic sera, or to the existence of endogenous immune complexes, for example. Aggregated immunoglobulins, particularly after repeated freezing and thawing, may also contribute to an increased background value. The problem of varying blank values is one reason for the greater sensitivity of protein quantitation in other body fluids such as urine, for example, as compared to serum. From the practical point of view it is usually

the problem of high blank values for serum samples which restricts the sensitivity in nephelometric analyses.

Detection of light scattering

Immunonephelometric techniques are suitable for automation and the methodological development within this field has, to a large extent, been dependent on the design of detection devices for scattered light. The initial instruments employed measurement of light scattering at an angle of 90° to the incident light beam, whereas later instruments took advantage of enhanced light scattering at lower angles (31° and less). In some instruments, the laser nephelometers, a helium-neon laser with an emitted wavelength of 632.8 nm is employed. In this device a high-intensity light is obtained at a reasonable cost. Furthermore, determinations at this wavelength will minimize potential autofluorescence from aromatic amino acids. Forward scatter is also measured at an angle of 31° or lower in laser nephelometers, which minimizes the problem of high blank values.

Further progress has been the development of rate nephelometry. In this modification the scatter is measured at two or more time points and the rate of scatter increase during the corresponding interval registered. This approach is based on the fact that the scatter is directly related to the size of the immune complexes, which in turn is dependent on the time of the antigen-antibody reaction. Plotting scatter against time gives a sigmoidal curve, the derivatives of which show a Gaussian-type shape. The rate of complex formation increases with increasing antigen concentration. In antigen excess, however, the rate levels off and decreases. High blank values are also of less importance in rate nephelometry, since the procedure implies registration of scatter over the sample background level.

Advantages and disadvantages

Immunonephelometry obviates various methodological difficulties. It is characterized by being simple to use and requiring relatively small sample volumes of unmodified body fluids for protein determination. The technique is sensitive, rapid and relatively inexpensive. Of particular interest are instruments designed during later years which use reagent volumes around 1–10 μl per analysis, thus reducing reagent costs. However, the high initial purchase cost restricts the use of nephelometric techniques to laboratories with a certain minimal body of analyses. Another advantage is that a large selection of monospecific commercial antisera are available which

makes the technique versatile with regard to the number of possible applications. Monoclonal antibodies have also been used in nephelometric estimations of proteins. The increased control of the specificity of the reaction has to be balanced against the possible disadvantage that saturation of antibodies in the solution occurs quicker than when conventional polyclonal antisera are employed. When saturation of antibodies occurs in antigen excess, as mentioned above, the direct relationship between antigen dose and scatter response is no longer valid and the response may even attain values within the normal operating range. This problem may be solved in several ways, e.g. by adding a second dose of antigen. If this results in an increased scatter value the initial value should be accepted whereas if no increase occurs or if decrease is registered, this indicates that the first reading was done at antigen excess and therefore should be discarded. The sample must then be reanalyzed at a higher dilution. In automated procedures, it is important to introduce control safeguards for the detection of values obtained in antigen excess.

Applications

Nephelometry has been applied to the quantitative determination of various protein and other antigens in blood serum, urine or cerebrospinal fluid such as lipoproteins, immunoglobulins, complement factors, rheumatoid factors and immune complexes. Measurement of light scattering has also been used for the determination of cell size, e.g. in the fluorescence-activated cell sorter (FACS). A recent development is the so-called microparticle-enhanced nephelometric immunoassay where antigen or antibody is conjugated to spherical, hydrophilic microparticles in the size range of 50–300 nm. This approach seems to provide higher sensitivity and lower reagent consumption as compared to conventional immunonephelometry and, if designed as an inhibition assay, haptens may also be quantified.

NEUROENDOCRINE REGULATION OF IMMUNITY

Bryan M Gebhardt, LSU Eye Center, Louisiana State University Medical Center School of Medicine, New Orleans, Louisiana, USA

J Edwin Blalock, Department of Physiology and Biophysics, University of Alabama at Birmingham, Alabama, USA

It is now clear that both the nervous system and the immune system have internal homeostatic mechanisms that control and regulate the functions of these systems and their responses to various stimuli. In recent years it has become apparent that some of these regulatory mechanisms act in an endocrine or paracrine manner, that is, neurotransmitters, neuropeptides and cytokines made in the nervous system either potentiate or inhibit immunologic responses and, correspondingly, mediators made by cells of the immune system act on cells of the nervous system (Figure 1).

The proposal that the immune system acts as a sensory organ, the so-called sixth sense, is finding increasing support and validation from studies in experimental animals and in clinical observations.

Figure 1 General schematic of the interactions between the nervous system and the immune system mediated primarily by soluble, secreted products of cells in each system. The prevailing view is that these two complex systems interact and share in the effort of promoting organismic homeostasis by the use of mediators produced in each system.

Indeed, the growing subdiscipline of psychoneuroimmunology is based on the study of the interactions between the nervous system and the immune system, and observations that immune responses to infectious agents and tumors may be modulated by mood, thought and behavior. In such a scenario, the immune system receives a noncognitive (antigenic) stimulus, responds, and sends signals (cytokines) to the nervous system which, in turn, reciprocates with immunoregulatory signals (neuropeptides, cytokines), some of which are the result of behavioral responses (Figure 2).

Neuromediators

Neurotransmitters

Anatomists and neuroscientists have long known that the neural innervation of lymphoid organs, such as the spleen, thymus, and lymph nodes, forms an important part of the homeostatic mechanism that regulates the size of, cell density in, and blood flow through these organs. A number of years ago it was noted that neurotransmission in nerve fibers innervating the spleens of animals undergoing immunization is increased, compared with that of spleens in animals not stimulated with a foreign antigen. Subsequently, the secretion of various neurotransmitters at the nerve terminals in lymphoid organs was found to be significantly increased following antigenic stimulation of the lymphoid organ and increased neural activity was correlated with lymphocyte activation and the initiation of an immune response (Figure 3). Such observations provided a basis for further investigation of the immunomodulatory role of hard wiring of lymphoid tissues by nerve fibers.

Figure 2 The immune system, typified by the schematic lymph node on the left, responds to antigenic stimuli and produces mediators that impact neural activity and neurosecretion of peptides and cytokines, which modulate the immune response to the antigen. This circuit is viewed as a bidirectional response system in which the immune system responds to noncognitive stimuli, such as infectious agents, and signals the nervous system, which responds to cognitive stimuli such as neurochemicals, cytokines, and physical and emotional stimuli and, in turn, signals the immune system.

Figure 3 Noradrenergic fibers from the spinal ganglia enter the spleen through the trabecular meshwork, distribute around and innervate areas of accumulated lymphocytes called the white pulp and the periarteriolar lymphatic sheaths, which consist of dense aggregates of lymphocytes. During antigenic stimulation, there is increased production of norepinephrine, substance P, somatostatin, and vasoactive intestinal peptide, which regulates blood flow and lymphatic activation.

In cell culture experiments, pharmacologic concentrations of neurosecretory substances such as epinephrine, norepinephrine, and 6-hydroxydopamine were found to suppress T lymphocyte mitogenesis and the differentiation of B cells into antibody-producing cells. The immunomodulatory effects of the neurosecretory substances observed *in vitro* may be a correlate of the increased neurosecretion that follows antigenic stimulation *in vivo*. It may be that neurosecretory mediators act on professional antigen-presenting cells such as macrophages and dendritic cells, reducing the secretion of interleukin 1 and ultimately reducing the intensity of the T cell response. It is also possible that neurosecretory substances act directly on antigen-stimulated lymphocytes (Figure 4). Several studies have shown that epinephrine and norepinephrine modulate lymphocyte responses in cell culture and it is thought that such effects may be mediated *in vivo* as well.

Neuropeptides

Vasoactive intestinal peptide (VIP) and substance P have been investigated extensively for their actions on the immunologic functions and responses of lymphoid cells. These peptides and others, including mediators of the hypothalamic-pituitary-adrenal (HPA) axis such as growth hormone, prolactin, adrenocorticotrophic hormone (ACTH), and various opioid peptides, have been shown to modulate immune responses *in vitro*. Indirectly, using antagonists and agonists of these mediators, *in vivo* modulation of immunity has also been observed.

VIP is secreted by cells in the digestive system; the functions of this peptide are vaso- and bronchodilation, glycogenolysis, and stimulation of the secretion of other neuropeptide mediators such as prolactin, growth hormone and luteinizing hormone. VIP enhances or dampens lymphocyte-mediated

Figure 4 Antigen presentation by macrophages and the lymphocyte response are modulated by noradrenergic activity. Norepinephrine and neuropeptides may act on the antigen-presenting macrophage, suppressing interleukin 1 (IL-1) production and thereby preventing lymphocyte activation and cell division. Alternatively, noradrenergic nerve activity may act directly on the lymphocyte, suppressing activation and mitosis.

responses; the particular response depends, in part, on the concentration of the peptide. T and B lymphocytes express membrane coreceptors of the integrin family of molecules and use these coreceptors in cell-cell recognition, cell migration, and binding to intercellular adhesion molecules on tissue cell membranes. VIP modulates the expression of integrin molecules, thus altering the migration and localization of lymphoid cells in the tissues (Figure 5). Overall, VIP seems to affect T lymphocyte responses more strongly than B lymphocyte responses.

Substance P is produced by various cells in the body, including neurons, macrophages and perhaps other antigen-presenting cells such as dendritic cells and Langerhans cells in the epidermis. Acting in an autocrine fashion, substance P significantly enhances the phagocytic capacity of macrophages. In other contexts, substance P stimulates DNA and protein synthesis in T cells, an effect that is antagonized by the substance P antagonist somatostatin.

A variety of other neuropeptides, including calcitonin gene-related peptide, galanin, neuropeptide Y and others, have been less well-studied in terms of their actions on the immune system and immune responses. Clearly, this is an area for further investigation.

In general, the majority of observations of the immunomodulatory effects of neuropeptides are obtained in cell culture systems in which the neuropeptide is added in various concentrations to lymphocytes in the presence of mitogens or antigens. The various inhibitory and/or stimulatory effects of the neuropeptides have been well-documented *in vitro* but have not been adequately translated to the *in vivo* situation. This is another area in which further investigation holds great promise for the expansion of our understanding of neuroimmunology.

Mediators of the hypothalamic-pituitary-adrenal axis

Hypothalamic dysfunction, hypophysectomy (removal of the pituitary gland) and adrenalectomy, separately or in combination, have dramatic and long-lasting effects on circulating immunocompetent cells. The absence of the pituitary gland eliminates the major source of various neuroendocrine hormones and neuropeptides, including luteinizing hormone, follicle-stimulating hormone, ACTH, prolactin, and growth hormone. The effect of hypophysectomy on the immune response is to alter the numbers of circulating leukocytes, reduce the capacity of both monocytes and macrophages to present antigens, and inhibit cytokine production by immunologically competent lymphocytes. Because the HPA axis is interrupted by removal of either the pituitary or the adrenal gland, glucocorticoids are no longer released into the circulation, thus eliminating a major regulatory factor that controls both the numbers of circulating leukocytes and the ability of these cells to

Figure 5 Vasoactive intestinal peptide (VIP) can alter lymphocyte movement and localization by stimulating the expression of intercellular adhesion molecule 1 (ICAM-1) and lymphocyte function-associated antigen 1 (LFA-1) on vascular endothelial cells and lymphocytes, respectively. Once receptor-ligand binding occurs, the lymphocytes can migrate from the blood vessel into the tissues.

participate in immune responses. In particular, the balance of immunoregulatory cytokine production is altered (Figure 6).

We and others have confirmed that certain white blood cells, especially mononuclear leukocytes (including lymphocytes), are the source of several of the neuropeptide hormones such as ACTH, luteinizing hormone, growth hormone and others (Figure 6). Recent studies using both cellular and molecular techniques revealed both the biological and molecular authenticity of leukocyte-derived neurohormones, including ACTH. Whether these leukocyte-derived neuropeptides can substitute for their HPA-derived counterparts *in vivo*, however, is still subject to some debate.

Much is known regarding the family of pro-opiomelanocortin (POMC) peptides, which includes the endorphins, enkephalins and ACTH. It has long been known that mononuclear leukocytes have receptors for ACTH, but it was not until recently that these receptors were shown to be functional. When both structural and functional correlates for ACTH receptors were demonstrated on cells of the adrenal cortex and on lymphocytes in a patient with the ACTH-

insensitivity syndrome, it became apparent that the presence of these receptors on the lymphocytes was not a happenstance. It is evident that these receptors enable lymphocytes to respond to, and to be regulated by, a neuropeptide hormone such as ACTH.

In vitro, ACTH inhibits the maturation of antibody-producing cells responding to the thymus-dependent antigen SRBC (sheep red blood cells); the maximal inhibitory effect occurs when the neuropeptide is present at the time of antigen exposure. However, the exact mechanism whereby ACTH exerts this inhibitory effect is not yet known, although it is tempting to speculate that receptor-mediated events either prevent T helper cells from making cytokines necessary for antibody-producing cell maturation or stimulate T helper cell production of an inhibitory cytokine that suppresses this maturation process (Figure 7). For example, activation of the ACTH receptors on T lymphocytes *in vitro* may inhibit production of a paracrine cytokine such as interleukin 4 (IL-4) or IL-5. These interleukins, among others, are required for the differentiation of B lymphocytes and the expression of isotype-specific antibody production. It is now possible to further study such sys-

Figure 6 Adrenocorticotrophic hormone (ACTH) produced in the pituitary gland stimulates the production of glucocorticoids by the adrenal glands (A). These naturally occurring steroids alter lymphocyte recirculation and cytokine production. Removal of the pituitary or adrenal gland interrupts the pathway involved in the production of ACTH and glucocorticoids (B). There is accumulating evidence that lymphocytes can produce biologically active neurohormones such as ACTH and thus may serve as an alternative source of such mediators.

Figure 7 ACTH suppresses antibody production *in vitro*. The hormone may act on the antigen presenting cell, the T helper cell, or the B cell, or all three, inhibiting cytokine-mediated growth and maturation of the antibody-producing cells.

tems using purified cell populations and to perform molecular analyses of gene expression in antigen-presenting cells, B cells, and T cells in these culture systems in order to determine more precisely the mechanisms of action of various neuropeptides.

Enkephalins and endorphins, which are peptides also derived from the POMC gene complex, also affect lymphocyte responses in cell culture. β -Endorphin enhances the proliferative response of rat lymphocytes to T cell mitogens and α -Endorphin suppresses the responses of human peripheral blood T lymphocytes to concanavalin A. These findings, which appear to be contradictory, only serve to highlight the importance of neuropeptide hormone concentration and the complexity of the cell culture systems used to study such interactions. Receptors for the naturally occurring opioids have been characterized on human and mouse lymphocytes. Both μ - and δ -class opioid receptor agonists have been shown to modulate immunoglobulin production and natural killer (NK) cell activity. The recent cloning and sequencing of an orphan opioid receptor on mouse lymphocytes confirms the existence of these receptors on the cells of the immune system and provides a

basis for future studies of the regulation of the immune system by naturally occurring opioids.

Growth hormone is a pituitary-derived neuropeptide that has important physiologic and homeostatic actions in the growth and differentiation of vertebrate organisms. Interestingly, in addition to overall regulation of organismic homeostasis, this neuropeptide has also been shown to modulate immune responses both *in vivo* and *in vitro*. *In vitro*, growth hormone promotes the differentiation of cytotoxic T lymphocytes in cell culture and enhances the proliferation of T lymphocytes in mixed lymphocyte culture in the presence of insulin. *In vivo*, growth hormone boosts immune responses in immunologically deficient animals, and has been shown to augment immunity and immune responses in normal and aged animals. In particular, this molecule is an important mediator in the proliferation of lymphocytes and the differentiation and enhancement of NK cell activity.

Prolactin is another pituitary-derived neuropeptide that has significant effects on lymphocyte responses *in vitro*. In high concentrations prolactin suppresses T cell proliferation, whereas in low concentrations it enhances this process. Lowering prolactin

concentration by hypophysectomy has an inhibitory effect on the antibody response and can inhibit the development of graft-versus-host disease in experimental animals. Table 1 is a compilation of neuromediators and their effects on immune responses.

Cytokines: a bridge between the nervous system and the immune system

Cytokines are cell-derived peptides that may modify the functions of the cells that secrete them, as well as the functions of other cells that have receptors for them. Table 2 lists a number of cytokines that are produced and act in both the nervous system and the immune system.

Some of our initial knowledge of cytokines that are produced by cells outside the nervous system but that have an apparent effect within the nervous system came from clinical observations. One early study demonstrated that during an acute phase response to a systemic bacterial infection, the associated fever and transient accumulation of inflammatory cells in the central nervous system (CNS) are mediated by IL-1 and IL-6. In addition, numerous anecdotal clinical observations pointed to effects of IL-2, interferon γ (IFN γ), tumor necrosis factor α (TNF α), and transforming growth factor β (TGF β) on the nervous system, even though these cytokines may be synthesized by cells outside of the nervous system.

Initially, many investigators sought pathways by

which exogenously-produced cytokines could be transported into the CNS. Although such pathways have now been identified and the circumstances under which the blood-brain barrier is sufficiently compromised to allow cytokines to pass from the blood into the CNS are known, it has also been shown that these pathways are not the only means by which these mediators come to be present in the brain. A number of years ago, it was demonstrated that IL-1 and IL-6 are produced by cells in the pituitary gland and that IL-1 may be the regulator of IL-6 production by these cells. Given the knowledge that these two cytokines are mediators of inflammatory reactions and that one or both can stimulate the production of glucocorticoids by the adrenal gland, it became obvious that nervous system-derived cytokines, including the interleukins, could be a direct link between the nervous system and the immune system.

Since these early observations were made, the literature regarding cytokine production and cytokine-producing cells in the nervous system has burgeoned. It is now known that astrocytes and microglial cells are sources of IL-1, IL-6, TNF α , colony-stimulating factor and TGF β , as well as a host of other chemokines whose structures and functions are now being clarified. More recently it has been shown that oligodendrocytes can also produce IL-1 and TGF β . The fact that astrocytes and microglial cells produce these cytokines in response to a variety of stimuli has caused some investigators to speculate that these cells represent an arm of the immune system within the nervous system. Certainly, the production of IL-1 and IL-6, as well as TNF α , by astrocytes and microglial cells makes a strong case for the role of these mediators within the nervous system in the regulation of proliferation, differentiation and the cellular response to infectious agents and injury as part of the effort to promote survival of the organism (Figure 8).

The link between the nervous system and the immune system is evident from the fact that nervous system-derived cytokines and chemokines act on immune cells outside the system. Thus, IL-1 and IL-6 produced by microglial cells and astrocytes may act on immune cells outside the nervous system and certainly can act on lymphocytes and macrophages that enter the nervous system during infectious processes. There is evidence that lymphocytes and antigen-presenting cells accumulate at sites of herpes virus infections in both the peripheral and the central nervous system; it seems likely that the mediators necessary both to promote the attraction of these immune system cells and to promote and enhance their immune function within the nervous system are

^a Much of what is known about these effects is derived from *in vitro* systems; a number of the neuromediators exhibit concentration-dependent effects on immunity and thus characterization of enhancement (↑) or suppression (↓) of a response depends on the conditions of the experiment.

Table 2 Cytokines that act in both the nervous system and the immune system

Cytokine	Nervous system		Immune system	
	Source	Action	Source	Action ^a
IL-1	Microglia, astrocytes, anterior pituitary cells, neurons	Glial growth, differentiation, stimulation of somatostatin and corticotropin-releasing factor (CRF) production	Macrophages, fibroblasts	T cell activation, leukocyte chemotaxis
IL-2	Microglia	Oligodendroblast proliferation, neurite outgrowth, stimulation of β -endorphin and ACTH secretion	T cells	T cell growth factor
IL-6	Microglia, astrocytes, anterior pituitary cells	Astrocyte growth, nerve growth factor production, ACTH and growth hormone production	T and B cells, macrophages, endothelial cells	T and B cell growth, differentiation, induction of acute phase protein production in liver
TNF α	Microglia, astrocytes	Astrocyte proliferation, stimulation of CRF production	Lymphocytes, macrophages	Mediation of inflammatory reactions, leukocyte chemotaxis
IFN				
α	Microglia, astrocytes	Inhibition of astrocyte proliferation, upregulation of MHC gene expression	T cells, fibroblasts, macrophages	B cell maturation, macrophage activation
β	Microglia, astrocytes			
γ	Neurons			
TGF α,β	Glial cells, neurons	Glial cell proliferation, neuron survival and neurotropism	Macrophages, T cells	Mediation of inflammatory reactions, control of cell differentiation

the cytokines made by glial cells within this system. It is known that astrocytes and microglial cells produce TNF α , which may modulate the expression of class I and class II major histocompatibility complex (MHC) molecules on some cell types in the CNS. Although there is no compelling evidence that neurons can be induced to express MHC class II molecules and the density of expression of MHC class I molecules by these cells is so low as to be difficult to measure, microglial cells, astrocytes, oligodendrocytes and perhaps other glial cells in the nervous system can express both MHC class I and class II molecules and, therefore, have the potential to act as antigen-presenting cells to lymphocytes attracted into the CNS by cytokines and chemokines (Figure 9).

In a recent series of studies, investigators have demonstrated the production of biologically active IFN γ by neurons in both the peripheral and the central nervous system. If confirmed, the production of so-called immune interferon by neurons provides yet another definitive link between the nervous system and the immune system and adds a new aspect to the bidirectional communication between these systems.

Psychoneuroimmunology

The mind-body connection

The recent resurgence of interest in studying our ability to ensure good health and to resist infections and diseases has been prompted in part by our increased understanding of regulatory mechanisms that affect the immune system and in part by our human desire to control and regulate our external and internal environments.

Psychoneuroimmunology is a subdiscipline of neuroimmunology that, to date, has attracted only a few mechanistically inclined immunologists. For the most part, the existing studies of the impact of emotional and environmental conditions, stress, and emotional disturbances on specific types of immunological responses have been initiated by psychiatrists, psychologists and behavioral biologists. Nevertheless, there are numerous published accounts of the effects of factors such as environmental stress, task/reward paradigms, crowding and overpopulation, and physical trauma on immunologic functions, including suppression of NK cell activity, antibody responses, and cell-mediated immune responses, as well as a

Figure 8 Production of cytokines by cells in the immune system (A) and nervous system (B). Some of the cytokines produced in each system act on cells within that system, but can also act on cells of the other system. Some of these cytokines cross the blood-brain barrier. In general, the cytokines involved mediate cell growth, cell differentiation, and serve as tropic factors in each system.

generalized reduction in the functioning of the immune system, relative to psychological well-being. Thus, evidence for such a link is growing.

The darker side of this area is represented by those who, in concert with the lay press, have promulgated the notion that the individual is capable of emotional control over the body's immune functions. In this context, it has been suggested that behavioral modification and one's emotional outlook can be used to defeat life-threatening diseases such as cancer, intractable pain and chronic debilitating viral infections including the acquired immune deficiency syndrome (AIDS). To date, there is no scientifically sound evidence that the nervous system, positive thoughts, neural activity and/or neuropeptides can separately or together defeat or reverse terminal conditions in

human beings. It is evident that a positive attitude and a good mental outlook undoubtedly help an individual's passage through a terminal disease, but it is not evident that such an outlook can prevent or cure such conditions. Unfortunately, this area of psychoneuroimmunology has been used as a basis on which to sell the public a variety of nostrums – putatively chemo- and/or psychotherapeutic – that may do more harm than good.

Summary

The science of neuroimmunology has become a bona fide division of immunologic thought and study in recent years. The observation that the nervous and endocrine systems exert regulatory actions on the

Figure 9 Induction of expression of MHC class I and class II molecules on glial cells allows these cells to present antigens to lymphocytes. Glial cells (microglia, astrocytes and oligodendrocytes) respond to such cytokines as $\text{IFN-}\gamma$ and $\text{TNF-}\alpha$, express class I and/or class II molecules, and present antigens to lymphocytes.

immune system, and on lymphocytes in particular, has provided a fertile area for investigation and holds great promise for the future, in terms of modulating immune responses in human beings. It is now clear that bidirectional communication between the nervous system and the immune system is mediated by shared neuropeptides and cytokines. Lymphocytes communicate with cells in the nervous system by producing neuroendocrine mediators and cytokines, and cells in the nervous system communicate with lymphocytes by producing neuroendocrine mediators and cytokines. The immune system can perceive non-cognitive stimuli such as infectious agents, foreign antigens, allergens, and perhaps tumors; signal the nervous system concerning the presence of the threat; and elicit a CNS response which, in turn, promotes and regulates the immunologic response to the invader. This balanced regulatory loop can be perceived as functioning in the normal organism as part

of the physiological goal of achieving homeostasis and resistance to disease processes and infections (Figure 10).

NEUROLOGICAL AUTOIMMUNE DISEASES

Barry GW Arnason, Department of Neurology, University of Chicago, Chicago, USA

Autoimmune diseases that affect the nervous system can be divided into three categories: those that alter function of 1) the nerve–muscle junction, 2) the peripheral nerves, and 3) the central nervous system.

Nerve–muscle junction

Myasthenia gravis

This disease is a T cell-dependent antibody-mediated process. The antibody is directed against the acetylcholine receptor situated on the muscle side of the motor nerve–muscle synapse. The acetylcholine receptor exists in two forms: extrajunctional (or fetal), found along the length of immature or denervated myotubes, and junctional, confined to synapses. The extrajunctional form has two α chains, a β chain and a γ chain. The junctional form has two α chains, a β chain and an ϵ chain. In myasthenia gravis the antibody response is chiefly directed against an epitope on the α chain known as the main immunogenic region but also to some extent against β and γ chains. Presence of antibodies directed against γ chain indicates that the initial response in myasthenia gravis is to the extrajunctional form of the receptor even though the disease is directed at the junctional form. The T cell component of the immune response is directed against numerous epitopes simultaneously, many of them on the α chain. The epitopes recognized by T cells differ from those recognized by the B cells that make the antibody.

When a motor nerve impulse reaches the terminal axon the neurotransmitter molecule acetylcholine is released into the synaptic cleft. Released acetylcho-

line binds to the acetylcholine receptor. This binding is followed by the opening of ion channels, sodium enters the muscle fiber, and this entry transduces a signal which leads to muscle contraction. In myasthenia gravis antibody cross-links the acetylcholine receptors which are then shed or pinocytosed. The end-result is that the muscle self-strips itself of its receptors. Some damage to the muscle end-plate by a complement-dependent mechanism also occurs. With loss of receptors comes weakness, the cardinal clinical feature of myasthenia gravis since nerve impulses, even though they lead to release of acetylcholine in normal amount, are not followed by muscle contraction. The muscle is not destroyed in myasthenia gravis and is fully capable of synthesizing new acetylcholine receptors. For this reason if the antibody can be eliminated, complete recovery can occur. The antibody can be eliminated either by downregulating the T cells that provide help to the B cells, by downregulating the B cells that actually make the antibody, or by removing it by means of plasmapheresis.

Thymic abnormalities are usual in myasthenia gravis. Germinal centers, which bespeak local antibody production, are found within the thymus in 70–80% of cases. Germinal centers are particularly frequent in young adult female myasthenics who carry the HLA-B8-DR3 haplotype. A thymic epithelioma (thymoma) is found in 10% of cases. Thymoma patients tend to be older than those without a thymoma and show no increase in any HLA haplotype. A third group of cases are elderly. Here males predominate, and the thymus is atrophic. Thymic myoid cells, a minor cell type within the thymus found at

the cortico-medullary junction and within the medulla, carry extrajunctional-type acetylcholine receptors. The disease may begin as an autoimmune response within the thymus directed initially against the extrajunctional acetylcholine receptor on thymic myoid cells and misdirected subsequently against the junctional acetylcholine receptor of muscle. Thymomas do not express acetylcholine receptors but do express a 153 kDa cytoplasmic protein that shares an epitope with the α chain of the acetylcholine receptor.

Antibodies to the acetylcholine receptor can be detected in the serum of 90% of cases of myasthenia gravis and they are quasi-specific for the disease. Serum from antibody-negative myasthenics sometimes will adoptively transfer disease to experimental animals, suggesting that in them an antibody directed against some other protein causes the disease. Antibody titer does not correlate with disease severity, indicating that factors other than antibody titer alone determine severity. It has been suggested that antibody directed against certain epitopes and in particular against the site on the acetylcholine receptor to which acetylcholine binds may be more potent than antibody directed against other epitopes. Myasthenics with such antibodies might have severe disease despite low titer. Alternatively, antibodies directed against the neuronal side of the myoneural junction could contribute to symptomatology, as might products released by macrophages and/or cytokines released by T cells. Macrophages are found at the myoneural junction at times of acute worsening of myasthenic symptomatology.

An experimental model for myasthenia gravis has been developed. Animals immunized with acetylcholine receptor develop antibodies to it and a myasthenic syndrome. At the onset of this experimental illness there is a brisk influx of macrophages into the myoneural junction region. At this time antibody titer is low. The macrophages disappear after a few days and the animal recovers clinically even while antibody titer continues to rise. A second wave of disease without a macrophage influx follows some weeks later at a time when the antibody titer has risen to a high level. In acute myasthenic crises in humans a similar macrophage influx is seen, and it seems likely that macrophage activity can contribute to the severity of disease. When serum from animals with experimental myasthenia gravis is injected into naive recipient animals myasthenia follows. Female recipients get more severe disease than male recipients and young recipients more severe disease than older ones, pointing to host factors independent of antibody as determinants of disease severity. Inhibi-

tors of macrophage function lessen the severity of adoptively transferred disease.

Immunotherapy with glucocorticoids, immunosuppressive drugs such as azathioprine or cyclosporine and, in acute emergencies, plasmapheresis provide the mainstays of treatment of human myasthenia gravis. Intravenous immunoglobulin G (IgG) treatment has also been reported to be beneficial. Early thymectomy is advocated by many, including this author. Cases associated with thymoma should be viewed as a remote effector of cancer. In them, the tumor should be removed though remission of disease following thymectomy is less common in patients with thymomas than in other cases.

Lambert-Eaton syndrome

This disease is a T cell-dependent antibody-mediated process in which the antibody is directed against voltage-gated calcium channels of the motor axon terminal. The response is directed chiefly against P-type channels, the major calcium channel type that mediates cholinergic transmitter release at the neuromuscular junction. Antibody cross-links the channels which are shed or pinocytosed, and hence stripped. Calcium entry into the terminal axon is critical for the release of acetylcholine and when calcium channels are lost, calcium entry is precluded. For this reason acetylcholine release fails, and weakness, a characteristic clinical feature of the Lambert-Eaton syndrome, ensues. There is a pathognomonic electromyographic abnormality in the Lambert-Eaton syndrome. Muscle contraction is weak when the motor nerves are stimulated at low frequencies. At higher stimulation frequencies the failure of calcium entry is in part overcome and the force of contraction increases. This is known as facilitation.

Fifty per cent of cases of the Lambert-Eaton syndrome occur on a background of cancer, most commonly small cell cancer of the lung. All small cell cancer cells carry several types of calcium channels including the P-type discussed above. In the Lambert-Eaton syndrome an antitumor response (which may to some extent hold the tumor in check) is misdirected against the motor axon terminal because both share identical calcium channels. Why only a small proportion of patients with small cell cancer develop antibody to the calcium channel is not known. In the other half of cases of the Lambert-Eaton syndrome (which are not associated with cancer) there is an over-representation of the histocompatibility alleles HLA-B8 and -DR3, indicating a genetically determined propensity to develop the disease. Many of these cases have other autoimmune diseases in addition to the Lambert-Eaton syndrome. Favorable response to plasmapheresis or intravenous

immunoglobulin in conjunction with glucocorticoids and immunosuppressive drugs is frequently observed.

Peripheral nerves

Guillain-Barré syndrome

The Guillain-Barré syndrome is characterized by acutely evolving weakness, loss of reflexes, and elevated spinal fluid protein. Weakness can be mild or so severe that total paralysis and respiratory failure ensue. The illness evolves over from 1 to 4 weeks, followed by a plateau period, and then by recovery over weeks to a year or more. Recovery is usually complete or nearly so, but 15% of cases are left with residual disability.

Approximately two-thirds of patients recall an antecedent acute infectious illness that has usually abated by the time neuropathic symptoms begin. The interval between the prodromal infectious episode, usually an acute respiratory illness or a dysenteric episode, is most often from 1 to 3 weeks, occasionally longer. Twenty per cent of cases follow *Campylobacter jejuni* enteritis. Ten per cent of cases follow the glandular fever-like syndrome caused by cytomegalovirus (CMV). At times, IgM antibody to CMV, presence of which argues strongly for infection with CMV in the immediate past, may be detected even when no recent illness can be recalled. It follows that the severity of the antecedent infection in no way correlates with the occurrence of a complicating polyneuritis. Five per cent of cases follow a surgical procedure. Usually blood transfusions have been given in such cases, and it is distinctly possible that CMV was introduced in the transfused blood. Five per cent of cases are associated with infectious mononucleosis, a disease caused by the Epstein-Barr virus (EBV). Two per cent of cases follow varicella (chickenpox) or zoster (shingles). Note that CMV, EBV, and varicella-zoster virus are all herpesviruses, suggesting some common thread. Marek's virus is an oncogenic herpesvirus of the chicken. An acute demyelinating polyneuritis which faithfully mimics the Guillain-Barré syndrome in its clinical, electrophysiologic and pathologic features follows infection of chickens with Marek's virus. Marek's virus also causes lymphomas, and it is noteworthy that in humans as well the Guillain-Barré syndrome may complicate lymphomatous disease, particularly Hodgkin's disease. Five per cent of Guillain-Barré cases have serologic evidence of active or recent mycoplasmal infection. A few cases have followed parenteral ganglioside administration.

Polyneuritis in association with HIV infection is being noted with increasing frequency. Onset occurs

most often shortly after seroconversion. HIV-positive patients frequently harbor other organisms (including CMV), and it is not clear whether the occurrence of the Guillain-Barré syndrome on a background of HIV infection is triggered by HIV itself or by some other organism.

A substantial proportion of Guillain-Barré syndrome cases can be accounted for by infection with a limited number of organisms. Why should these infections cause the disease or predispose toward it when other infections do not? In this regard there has been considerable interest in the concept of molecular mimicry. It is hypothesized that there are close sequence similarities between small regions of proteins of infectious agents and small regions of host proteins. The infection triggers an immune response to the sequence on the infectious organism which then cross-reacts with the analogous region of the host protein. In this way tolerance to self is broken and a tissue-destructive autoimmune response ensues. Molecular mimicry has been demonstrated in several autoimmune diseases so that the concept is an attractive one in the Guillain-Barré syndrome; unfortunately, firm evidence to support it is lacking.

Acute inflammatory demyelinating polyneuropathy (AIDP) Four subtypes of the Guillain-Barré syndrome are recognized. Of these, by far the commonest in North America and Europe is acute inflammatory demyelinating polyneuropathy (AIDP). AIDP is characterized by weakness, sensory loss, cranial nerve involvement, and sympathetic nervous system compromise. The characteristic pathologic feature is one of scattered inflammatory cellular infiltrates within nerves and roots composed primarily of T cells and macrophages. At sites of inflammation there is destruction of peripheral nerve myelin by the invading macrophages. Destruction begins on the abaxonal surface, i.e. furthest from the axon. The macrophages secrete proteases, reactive oxygen and nitrogen species, and complement components, all of which contribute to myelin damage. Acute demyelination blocks nerve impulse conduction, hence the paralysis. When the inflammatory response is particularly intense there may be axonal destruction as well. Activated T cells and activated macrophages are found in the blood at the onset of AIDP.

After a few weeks the nerves remyelinate, a relatively rapid repair process. When there is superimposed axonal destruction, recovery may be delayed over months to a year or more since regrowth of axons is a slow process.

A model for AIDP known as experimental allergic neuritis (EAN) has been developed. Animals immunized with the P₀ and/or P₂ proteins of peripheral

nerve myelin develop an acute demyelinating disease which faithfully mimics the human one clinically, pathologically, and electrophysiologically. EAN is mediated by CD4⁺ T cells acting in conjunction with macrophages, but only a minority of AIDP patients demonstrate T cell or antibody responses to the P₀ or P₂ proteins, so the model is imperfect.
